Clinical Manifestations and Medical History
Fundamentals of Treatment

The clinical and laboratory features of the three most common hereditary bleeding disorders—hemophilia A (factor VIII deficiency), hemophilia B (factor IX deficiency), and von Willebrand disease (VWD)—are discussed in this chapter. Hemophilia A and hemophilia B are both caused by a functional deficiency of a plasma protein inherited in an X-linked manner. Because these two proteins, factor VIII and factor IX, are part of the tenase complex that subsequently activates factor X (see Chapter 27), the clinical features and many of the diagnostic considerations for hemophilia A and B are similar. Thus these two types of hemophilia are discussed together, although the treatment of each is presented separately. The last part of this chapter is devoted to VWD. Because von Willebrand factor (VWF) and factor VIII exist as a circulating noncovalent complex in plasma, historically they copurified during plasma fractionation. In fact, for many years, severe VWD and hemophilia A were treated with the same plasma-derived therapeutic products. As the products to treat hemophilia A became more pure, factor VIII was subfractionated away from its carrier protein VWF, thereby making high-purity factor VIII products unsatisfactory for the treatment of VWD. The most commonly used products to treat hemophilia A contain recombinant factor VIII and do not contain VWF. To treat severe VWD, intermediate-purity plasma-derived concentrate containing both VWF and factor VIII or, in some regions of the world, purified plasma-derived VWF concentrates are available to treat deficiency of VWF when replacement therapy is indicated. Recombinant VWF is currently being investigated in clinical studies and will likely be available to patients in the near future.

HEMOPHILIA A AND HEMOPHILIA B

Hemophilia A and hemophilia B are the most common severe inherited bleeding disorders. Historically, hemophilia has been recognized as an entity since biblical times.[1] Use of the term *hemophilia* was ascribed to Schönlein in the 1820s.[2] Progressive insight into the pathophysiologic course of the disease has led to the development of powerful tools for diagnosis and agents for improved therapy, as well as the need to minimize the primary and secondary complications of the disease and its therapy.[3] The prolonged clotting time of hemophilic blood was first noted in 1893,[4] and the associated decrease in factor VIII levels in hemophilia A was initially identified in 1947.[5,6] In 1952 levels of factor IX were found to be decreased in *Christmas disease*, which was the early term used to denote hemophilia B because it was the surname of the first patient diagnosed with the disease.[7]

Early therapy for hemophilia was primarily supportive, but after the observation in the 1930s that administration of plasma corrected the clotting time of hemophilic blood, treatment evolved to include transfusion with whole blood and plasma to achieve improved clotting function.[8,9] The modern era of treatment began in 1964 with the discovery of cryoprecipitate[9] and plasma fractions containing factor IX[10] and their use to treat bleeding episodes in hemophilia. More purified products were introduced in 1965 and were referred to as factor VIII concentrates (containing both factor VIII and VWF).[11,12] The next major improvements in replacement therapy were the result of attempts to limit transfusion-related viral infections during the 1980s, which included improved donor selection, heat treatment of the product, and further refined purification schemes.[13-15]

In 1984 and 1985 the genes for factor VIII and factor IX were cloned,[16-19] and in 1989, recombinant factor VIII was first used clinically.[20,21] In recent years more highly purified factor IX and recombinant factor IX products have been developed. With the advent of recombinant products, patients with hemophilia could more readily and safely be treated with primary[22-24,25,26] and secondary prophylactic therapy.[27] Such vigorous treatment programs markedly reduce the likelihood of spontaneous bleeding episodes and the progression of hemophilic arthropathy. Thus prophylaxis continues to be the preferred approach to patients with severe hemophilia.

The landscape of hemophilia treatment is changing significantly. New progress has been made in the development of recombinant products based on the prolongation of the half-life of factors VIII and IX. Several clinical trials in adults and children are ongoing, and it is likely that some of these new products will be available to patients shortly. Additionally, a major breakthrough in hemophilia therapy was recently made with the report of a successful gene therapy clinical trial for hemophilia B with long-lasting, sustained coagulation factor IX levels.[27a]

Pathophysiology

The structure and function of factors VIII and IX in the coagulation pathway were outlined in Chapter 27. Both factors are crucial for normal thrombin generation. The classic representation of hemostasis shows factor VII together with tissue factor activating factor X; however, subsequent studies suggested that the primary physiologic pathway of activation of factor X by tissue factor and factor VII is through the activation of factor IX.[28,29] Activated factor IX complexes with factor VIIIa, calcium, and phosphatidylserine on physiologic membranes to generate factor Xa, which subsequently participates in formation of the prothrombinase complex. Thus, physiologically, the tissue factor pathway of factor X activation requires factor VIII and factor IX for normal thrombin generation, and the absence of either protein severely impairs the ability to generate thrombin and fibrin. This absence is not identified by use of the classic prothrombin time; the prothrombin time is normal in patients with hemophilia A or hemophilia B.

After injury the initial hemostatic event is formation of a platelet plug, and the subsequent generation of fibrin is crucial to prevent continued oozing. Because of the primary clotting factor deficiency in either hemophilia A or hemophilia B, the propagation phase of coagulation is impaired, and clot formation is delayed and is not robust. Thus patients with hemophilia do not bleed more rapidly; rather, there is delayed formation of an abnormal clot.[30] Thrombin is crucial for platelet aggregation, fibrin generation, clot retraction, and activation of factor XIII. Because thrombin generation in hemophilia is markedly delayed, hemorrhage may occur after minimal or unknown trauma. Deep bleeding into joints and muscles is characteristic of hemophilia. In hemophilia the clot formed is often friable, and rebleeding is a common observation in inadequately treated patients. Medications such as aspirin and other nonsteroidal antiinflammatory drugs may alter platelet function and further impair hemostasis in affected individuals and are therefore contraindicated.[31]

Demographics and Classification

Hemophilia occurs in approximately 1 in 5000 males.[32-34] Of all patients with hemophilia, 80% to 85% have hemophilia A, and 10% to 15% have hemophilia B. Hemophilia shows no apparent racial predilection and appears in all ethnic groups.

The severity of hemophilia is classified on the basis of the patient's baseline level of factor VIII or factor IX. One unit of each factor is defined as the amount found in 1 mL of normal plasma. Factor levels are often expressed as a percentage of activity, with a 100% level (100 U/dL) being equal to the activity found in 1 mL of normal plasma. Severe hemophilia is characterized by a factor level of less than 1 U/dL (<1%). In moderate hemophilia the clotting factor level is between 1 and 5 U/dL, and in mild hemophilia factor VIII or IX levels are greater than 5 U/dL. This classification provides a rough guide for the patient's expected rate of occurrence of bleeding episodes. Although the correlation is not perfect, the clinical phenotype usually corresponds to the factor level. Patients with severe hemophilia often have bleeding episodes after minimal or unknown trauma, with children experiencing unprovoked muscle and joint bleeding between one and six times per month. With more aggressive prophylactic administration of factor VIII, instances of bleeding are markedly reduced. Patients with moderate hemophilia will have bleeding after mild to moderate injuries, whereas mild hemophilia may often be undiagnosed for many years, and these patients may have bleeding only after significant trauma or at the time of surgery.

Clinical Manifestations

Approximately 30% of male infants with hemophilia have bleeding with circumcision.[35] In some reports as many as 2% to 3% of neonates with hemophilia may experience an intracranial hemorrhage.[36,37] It is important to prevent head trauma during delivery. Forceps or vacuum extraction should be discouraged.[36,38] In the majority of patients hemophilia is diagnosed at birth because of a family history, although in approximately a third of patients the occurrence of hemophilia represents a new mutation.[39] In these latter patients the diagnosis is often made when the child begins to crawl and walk. The usual initial symptoms include easy bruising; oral bleeding, especially from a torn frenulum; hemarthrosis; and intramuscular hemorrhage. When the diagnosis of hemophilia is suspected on the basis of either clinical findings or a positive family history, the initial diagnostic studies should include determination of the prothrombin time, partial thromboplastin time (PTT), fibrinogen or thrombin time, platelet count, and studies to identify VWD (see Chapter 29). If the PTT is prolonged, assays for factor VIII and factor IX should be performed. The presence of an antibody inhibiting either factor VIII or IX can be ruled out by mixing normal plasma in equal volume with the test plasma, incubating the mixture for 30 to 60 minutes, and repeating the PTT to be sure that it has been normalized (mixing study). The specific assays for factor VIII and factor IX are not as easily affected by difficult venipuncture and are therefore more reliable. Factor VIII and VWF levels may be elevated by stress and inflammation, however, and repeated studies may be necessary to establish the diagnosis and the severity of the disorder.

Specific types of bleeding are described in the following paragraphs. In general, the clinical bleeding episodes associated with deficiency of factor VIII or factor IX are identical.

Musculoskeletal Bleeding

Although patients with hemophilia may bleed in any area of the body, the hallmark of hemophilia is deep bleeding into joints and muscles.[40] The occurrence of such hemorrhage usually corresponds to the severity of the clotting factor deficiency in patients with either hemophilia A or hemophilia B. Without prophylactic factor treatment, patients with severe hemophilia may have a bleeding episode as often as once or twice per week. Bleeding occurs most commonly into the joint space, a condition referred to as *hemarthrosis*. These joint hemorrhages usually begin when the child reaches the toddler age. As the toddler attempts to maintain an upright position, the ankle becomes particularly prone to hemorrhage. Thus in toddlers the ankle is the most common site of hemorrhage, with the knee being the second most common. As the child grows older, the most frequent bleeding sites are the knees and elbows.

Patients who sustain hemarthrosis usually first note an aura of tingling or warmth, followed shortly thereafter by increasing pain and decreased range of motion of the joint as the joint capsule becomes progressively distended.[41-43] As children get older, they are often able to tell their parents and the physician when a hemorrhage is beginning to occur, even in the absence of significant signs on physical examination. In young children who are unable to verbalize symptoms, severe pain and distention of the joint space often occur before the location of the hemorrhage can be easily determined. On examination pain and limitation of range of motion of the joint are obvious and followed by the development of warmth, swelling, and tenderness.

Prompt, early coagulation factor replacement therapy is the key to minimizing long-term complications of these hemorrhages. Patients with severe hemophilia are increasingly being treated prophylactically to prevent most bleeding episodes (discussed later). Prompt aspiration of hip hemarthrosis should be performed if joint distention is present to reduce the risk for avascular necrosis of the femoral head (a rare event). As children and their parents become familiar with the early symptoms of bleeding, aggressive early treatment can be given to reduce the degree of joint damage. If the child experiences repeated hemorrhage within a joint, chronic effusion and hyperemia often occur, and an aggressive secondary prophylactic therapy program may be needed to return the joint to a more normal state of recovery.[27] Severe chronic arthropathy may develop in older children and adults who have not received aggressive early treatment. These individuals often experience pain very early with little swelling. The joints of younger children are usually more distensible, and massive joint swelling may be observed. Splinting and application of ice packs as auxiliary measures may provide a modicum of relief but are not substitutes for early coagulation factor replacement therapy. When the physician has doubts, treatment should be initiated; it is not appropriate to watch and wait because damage to the joint can start early in life.

The clinical diagnosis of intramuscular hematoma is often elusive. Such hemorrhage occurs deep within the body of the muscle and is associated with a vague feeling of pain on motion. Because the bleeding is not in a closed space, the mass may be difficult to palpate, although the circumference of the affected limb is generally increased. Muscle hemorrhage should be considered to be as severe as hemarthrosis because it may result in severe muscular contractures as a result of fibrosis and atrophy or even pseudotumor formation. Muscle weakness also predisposes patients to joint hemorrhage. Appropriate replacement therapy is critical for reducing the size of the hematoma, and physical therapy is important to restore normal range of motion and prevent fibrosis of the muscle.

Iliopsoas bleeding is a particularly troublesome form of intramuscular hemorrhage. A patient with an iliopsoas hemorrhage is generally seen with vague symptoms of lower abdominal or upper thigh discomfort. The patient may have a characteristic gait; the hip is flexed and inwardly rotated. On examination the patient is unable to extend the hip, but usually both internal and external rotation of the hip joint is normal; the latter finding often distinguishes an iliopsoas hemorrhage from a true hemarthrosis of the hip joint. The diagnosis is made clinically by these findings and should be confirmed by either ultrasonography or computed tomography (CT).[44] Appropriate treatment is crucial; iliopsoas hemorrhages may be life threatening because large volumes of blood can be lost into the retroperitoneal space. Physical examination demonstrates loss of hyperextension of the hip. If an iliopsoas hemorrhage is identified, an aggressive infusion program should be initiated and maintained for 10 to 14 days or longer, followed by at least several months of prophylactic therapy until clinical and radiographic evidence demonstrates resolution.

Life-Threatening Hemorrhages

Bleeding episodes of the central nervous system (CNS), bleeding into and around the airway, and exsanguinating hemorrhage are the most common causes of life-threatening hemorrhage in hemophilia. The first element of treatment is prompt therapy with clotting factor concentrate to bring the plasma clotting factor level to normal. CNS hemorrhage may occur without known trauma, and early symptoms may be minimal. Thus therapy should be initiated before radiologic evaluation or lumbar puncture; when there is any doubt, it is better to treat immediately.[45-47] Rapid performance of CT is often critical in the early diagnosis of intracranial bleeding, although an astonishingly large volume of blood can be present within the cranium in infants with relatively few neurologic findings. Treatment of life-threatening hemorrhage involves replacement therapy to achieve a level of 100 U/dL for factor VIII and factor IX, maintenance of adequate hemostatic levels (>50 to 60 U/dL) for a minimum of 14 days, and a more prolonged period of prophylactic therapy for an additional 2 to 3 weeks or longer to ensure resolution of the underlying event (Table 31-1). Patients with intracranial hemorrhage should receive prophylaxis for at least 6 months after the more intense initial therapy and may benefit from lifelong prophylaxis.

Preparation for Surgery

Preparation of a hemophilic patient for surgery includes a careful history and physical examination, measurement of inhibitor titer, careful determination of the incremental recovery and half-life after infusion of the appropriate clotting factor (VIII or IX), and assurance that adequate amounts of coagulation factor replacement material are available, as well as red cells if a transfusion is needed.[48] Before surgery the replacement materials should be infused to achieve a level of 80 to 100 U/dL for factor IX and 100 to 150 U/dL for factor VIII; levels should be maintained at greater than 50 to 60 U/dL for 7 to 10 days postoperatively. Lower doses to maintain levels at greater than 20 to 30 U/dL for an additional 1 to 2 weeks may then be used and continued until healing has occurred (see Table 31-1). Because recovery of recombinant factor IX activity is less than that of therapeutic plasma-derived

TABLE 31-1 Treatment of Specific Hemorrhages in Hemophilia

Type of Hemorrhage	Hemophilia A	Hemophilia B[*]
Hemarthrosis[†]	*50 U/kg* factor VIII concentrate initially,[‡] 20 U/kg the following day; consider additional treatment every other day, depending on response	*80 U/kg* factor IX concentrate initially, 40 U/kg the following day; consider additional treatment every other day, depending on response
Muscle or significant subcutaneous hematoma	*50 U/kg* factor VIII concentrate; may need 20 U/kg every other day until well resolved	*80 U/kg* factor IX concentrate; may need 40 U/kg every other day until well resolved
Mouth, deciduous tooth, or tooth extraction	*20 U/kg* factor VIII concentrate (40 U/kg if molar extraction), antifibrinolytic therapy; remove loose deciduous tooth	*40 U/kg* factor IX concentrate (80 U/kg if molar extraction), antifibrinolytic therapy; remove loose deciduous tooth
Epistaxis	*Apply pressure* for 15-20 min, nosebleed QR, pack with petrolatum gauze, antifibrinolytic therapy; 20 U/kg factor VIII concentrate if preceding measure fails	*Apply pressure* for 15-20 min, nosebleed QR, pack with petrolatum gauze, antifibrinolytic therapy[§]; 30 U/kg factor IX concentrate if preceding measure fails
Major surgery, life-threatening hemorrhage (e.g., central nervous system, gastrointestinal, airway)	*50-75 U/kg* factor VIII concentrate, then initiate continuous infusion of 3 U/kg/hr to maintain factor VIIII > 100 U/dL for 24 hr, and then give 2-3 U/kg/hr for 5-7 days to maintain the level greater than 50 U/dL and an additional 5-7 days at a level >30 U/dL (bolus dosing to maintain these levels is acceptable); monitor factor VIII levels	*80-100 U/kg* factor IX concentrate, then 20-40 U/kg every 12-24 hr to maintain factor IX >40 U/dL for 5-7 days, and then >30 U/dL for 5-7 days[‖]; monitor factor IX levels
Iliopsoas hemorrhage	*50 U/kg* factor VIII concentrate, then 25 U/kg every 12 hr until asymptomatic, and then 20 U/kg every other day for a total of 10-14 days[¶]	*80 U/kg* factor IX concentrate, then 20-40 U/kg every 12-24 hr to maintain factor IX > 40 IU/dL until asymptomatic, and then 30 U/kg every other day for a total of 10-14 days[‖,¶]
Hematuria	*Bed rest*, 1.5 × maintenance fluids; if not controlled in 1-2 days, 20 U/kg factor VIII concentrate; if not controlled, prednisone if human immunodeficiency virus negative	*Bed rest*, 1.5 × maintenance fluids; if not controlled in 1-2 days, 30 U/kg factor IX concentrate; if not controlled, prednisone if human immunodeficiency virus negative

[*] Dosing of recombinant factor IX should be increased to 1.3 to 1.5 times the recommended doses or, preferably, be based on an individual in vivo recovery study.

[†] For hip hemarthrosis, orthopedic evaluation for possible aspiration is advisable.

[‡] For mild or moderate hemophilia, desmopressin, 0.3 μg/kg, should be used instead of factor VIII concentrate if patient is known to respond with a hemostatic level of factor VIII; if repeated doses are given, monitor factor VIII levels for tachyphylaxis.

[§] Do not give antifibrinolytic therapy until 4 to 6 hours after a dose of prothrombin complex concentrate.

[‖] If repeated doses of factor IX concentrate are required, use highly purified, specific factor IX concentrate.

[¶] Repeat radiologic assessment should be performed before discontinuation of therapy.

factor IX, 1.2 to 1.5 times the dose should be administered if using recombinant factor IX.[49,50]

Miscellaneous Hemorrhages

A common manifestation of hemophilia is oral bleeding, whether from a torn frenulum in a young child or after tooth extraction in an older patient. Replacement therapy to achieve a factor level of 30 to 40 U/dL is adequate for initial therapy. Because the mucosae of the oral cavity contains abundant fibrinolytic activity, therapy with antifibrinolytic agents (aminocaproic acid [Amicar] or tranexamic acid [Cyklokapron and Lysteda]) is useful to stabilize the clot until the wound has healed.[51-53]

Hematuria can be a particularly troublesome problem. Blood in the urine may arise spontaneously, and determination of an actual bleeding site is often difficult. Therapy is also controversial. Replacement therapy with 40 to 50 U/kg of factor VIII or IX followed by bed rest is generally advisable after other common causes of hematuria have been ruled out. Treatment with corticosteroids may be helpful.[54] Sudden abdominal or flank pain should be investigated for the possibility of ureteral obstruction and hydronephrosis secondary to bleeding. Antifibrinolytic agents are not recommended in hematuria because of the risk they present for ureteral obstruction.

Gastrointestinal bleeding is an occasional complication of hemophilia. All the common causes of gastrointestinal bleeding can occur in patients with hemophilia, as well as spontaneous hemorrhage after no known insult. An initial episode of gastrointestinal hemorrhage requires that the patient receive a thorough gastrointestinal evaluation after the acute bleeding is controlled with replacement therapy. If substantial blood loss has occurred, patients should be treated with high doses of concentrate as though they were at risk for life-threatening hemorrhage.

Long-Term Complications of Joint Bleeding

Chronic arthropathy is the major long-term disabling complication of hemophilia. The articular surface of a normal joint is lined with cartilage that is lubricated by synovial fluid produced by the synovial lining of the joint. A thick fibrous capsule protects the joint. The natural history of hemophilic arthropathy is one of a cycle of recurrent hemorrhage into a "target" joint leading to synovial thickening and friability, followed by additional hemorrhage into the joint.[41,42,55] After a joint hemorrhage, proteolytic enzymes are released by granulocytes into the joint space.[56] In addition, heme iron is ingested by macrophages and may contribute to inflammation by the release of oxidative products. The synovium of the joint, originally the width of a single cell, proliferates in response to inflammation and develops frondlike projections into the joint.

These projections are by nature friable and bleed with minimal trauma, thus setting up a vicious cycle of recurrent hemorrhage. With recurrence of hemorrhage there is further release of substances injurious to the joint cartilage, which causes it to develop a roughened, lunar landscape–like surface. As the cartilage erodes, the joint space becomes narrowed. In recent years the pathophysiology of hemophilia arthropathy has been better characterized at a molecular level; not surprisingly, it shows some similarities with other inflammatory processes that are associated with joint diseases such as rheumatoid arthritis.[57]

On examination, the clinical findings depend on the stage of arthropathy that has developed. The early stages are characterized by synovial thickening with little evidence of joint damage. With synovitis alone, the range of motion of the joint is nearly normal, although recurrent bleeding episodes usually result in weakness of the proximal muscles. With time, however, proliferative changes become associated with erosion of the cartilage. The patient at this stage may note the development of arthritic symptoms that are often difficult to distinguish from joint bleeding. Crepitus and decreased range of motion are prominent findings on physical examination. At this stage proximal muscle weakness is accentuated because of the inability of the joint to attain full range of motion. Finally, with progressive bleeding and further narrowing of the joint space, the joint fuses.

This progression of joint disease was once commonly seen in hemophilia centers throughout the United States and other countries. The most commonly affected joints were the knees, ankles, and elbows. With the development of modern concentrates for replacement therapy, home therapy, and prophylactic therapy, this cycle has now been disrupted in the vast majority of children with severe hemophilia. Primary prophylactic therapy and early diagnosis and treatment of joint hemorrhage have limited the number of "target joints" that develop. When a joint becomes a target, hemorrhage into that joint must be treated vigorously and the joint must be carefully watched for the cycle of rebleeding every 1 to 2 weeks that is characteristic of incompletely treated hemarthrosis. If evidence of early synovitis or loss of range of motion is present, a secondary prophylactic therapy program of every-other-day treatment for 30 to 90 days is often helpful for "cooling down" the affected joint and allowing healing to occur.[27]

Alternatively, a lifelong prophylactic therapy program to prevent spontaneous, severe joint bleeding may be started in young infants (discussed later), a modality that is currently widely used in the United States and other developed nations.[58] If medical therapy fails, synovectomy frequently reduces the occurrence of bleeding and may prevent progression of the joint disease. With the advent of arthroscopic means to perform synovectomy, this procedure has been more readily performed with reduced morbidity; equally important, early mobilization of the affected joint allows more rapid return of range of motion.[59,60] Another procedure in which various radioisotopes are used to reduce the mass of inflamed synovium is termed *radioactive synovectomy*.[60] This approach is recommended for patients with inhibitors. Fewer radioactive synovectomies are now performed because of the development of acute lymphoblastic leukemia in two children who underwent this procedure.[61] When aggressive medical and less invasive surgical management fails to halt progression of the joint disease, some adults have benefited from joint replacement.[62-64]

If pain and bleeding are severe in a joint with minimal range of motion, joint fusion may provide a significant decrease in pain and rebleeding. A critical element in the care of patients with chronic joint disease is the need for a team approach to the problem because the care of these children requires the combined expertise of an orthopedic surgeon, physical therapist, nurse, social worker, and hematologist to achieve optimal results.

Symptomatic Carriers

Although the usual patient with hemophilia A or hemophilia B is a male, carriers of a factor VIII or factor IX gene mutation may also be symptomatic. Known carriers should have their levels of clotting factor measured at least once to determine whether they are at increased risk for clinical bleeding episodes. There are several possible explanations for the observation of a female patient with moderate or severe deficiency of factor VIII or factor IX.[65-68] Skewed lyonization of a carrier female is the most commonly accepted explanation. As predicted by the Lyon hypothesis, the X chromosome in each female cell is randomly inactivated early in embryonic development; by chance, some carriers of hemophilia will have a high percentage of inactivated normal X chromosomes. The active abnormal X chromosome will result in deficient synthesis of factor VIII or factor IX. Other explanations for the presence of hemophilia A or B in a phenotypic female include testicular feminization of a genotypic male,[69,70] Turner syndrome with the genotype XO,[71-72] an X autosomal translocation with skewed X inactivation,[73] and a daughter of a maternal carrier and a father with hemophilia A. Factor VIII deficiency is also found in type 2N VWD as a result of mutations in the factor VIII–binding region of the VWF protein.[74]

Laboratory Evaluation

Severe hemophilia A or hemophilia B is easily identified by a markedly prolonged PTT and the absence of either factor VIII or factor IX. The diagnosis of mild hemophilia A or hemophilia B may be more difficult to make because the newborn has a slightly prolonged PTT secondary to a physiologic reduction in vitamin K–dependent factors such as factor IX. In addition, the stress of delivery and other neonatal problems may transiently elevate factor VIII levels into the normal or nearly normal range. Thus in the absence of clinical bleeding, mild deficiencies may be identified only after repeated testing in the weeks or months after birth (see Chapter 29). VWF testing must be done to distinguish mild or moderate factor VIII deficiency secondary to hemophilia from deficiencies of factor VIII secondary to VWD.

Partial Thromboplastin Time

The PTT measures all the procoagulant clotting factors except factor VII and factor XIII (see Chapters 27 and 29). In general, the PTT is most sensitive for deficiencies of the "intrinsic" pathway.[75] In general, commercial PTT reagents have good sensitivity for factor VIII deficiency, but their sensitivity for factor IX deficiency is more variable.[76-78] Use of some of these reagents will give normal PTTs even with factor IX levels of 15 to 20 U/dL. Because the hemostatic level of factor IX is approximately 30 U/dL, mild or moderate factor IX deficiency may be missed. Thus if hemophilia is suspected, a factor IX assay should be performed even if the PTT is normal. The clinical laboratory technician should study the sensitivity of each lot of PTT reagent to be able to advise the clinician about the likelihood that a normal PTT implies normal clotting factor levels. In patients with severe hemophilia A or hemophilia B, the PTT is generally prolonged to two to three times the upper limit of the normal range. The prolonged PTT will correct to within the normal range when the reagent is mixed 1 : 1 with normal plasma. Failure of the PTT to correct on 1 : 1 mixing of the reagent with normal plasma implies the presence of an anticoagulant (e.g., lupus inhibitor, antibody to factor VIII or IX, or heparin). The presence of a specific anti–factor VIII or anti–factor IX inhibitory antibody is described in more detail later.

Specific Assays for Factor VIII and Factor IX

Functional assays for factor VIII and factor IX are performed on plasma samples that contain no factor VIII or factor IX, respectively (either hemophilia A or hemophilia B plasma); alternatively, normal plasma from which the respective clotting factor is selectively removed by a monoclonal antibody can be used.[79] If adsorbed plasma is used for factor VIII–deficient plasma, the VWF content of that plasma should be normal. A standard curve is constructed with the use of normal plasma, with the 100% point being a 1 : 10 dilution of normal plasma. Serial dilutions of this normal plasma should usually be linear through a dilution of 1 : 640 or 1 : 1280 when plotted semilogarithmically versus the clotting time. Serial dilutions of the patient's plasma are compared with this normal curve and expressed in units per deciliter. One unit is the amount of factor VIII or factor IX present in 1mL of normal plasma.

Immunoassays for factor VIII and factor IX are sometimes performed to identify dysfunctional proteins, also known as cross-reacting material (CRM) positive (+) variants. The majority of patients with severe hemophilia A have undetectable levels of factor VIII protein, but some patients with mild or moderate hemophilia A possess levels of factor VIII protein that are detectable with an immunoassay.[80-82] In hemophilia B approximately 50% of patients will have detectable or even normal levels of factor IX antigen and therefore have true CRM + variants.[83,84] Immunoassays are not usually required for the clinical management of these disorders because the coagulant-based assays predict the functional concentration of these clotting factors.

Inhibitory Antibodies to Factor VIII or Factor IX

Inhibitor development is one of the most feared complications of hemophilia. The presence of a factor VIII or factor IX inhibitory antibody is usually suspected when the PTT does not correct to normal after being mixed 1 : 1 with normal plasma. Because of the kinetics of the inhibitory antibody, this mixture should be incubated 60 minutes before the PTT is performed. When a low-titer inhibitory antibody is identified, the PTT performed on a 1:1 mixture with normal plasma may initially be prolonged only by several seconds, but when the mixture is incubated for 1 hour, the PTT may be as long as or even longer than the PTT when it was originally performed on the patient's plasma.

Specific assays for factor VIII or factor IX antibodies are performed with the Bethesda assay. Dilutions of the test plasma are mixed with normal plasma and incubated for 120 minutes. A standard factor VIII or factor IX assay is then performed. One Bethesda unit is defined as the amount of antibody that will inactivate 50% of the normal factor VIII or factor IX in 2 hours when the residual factor VIII or factor IX level is between 25 and 75 U/dL.[85] The dilution of the test plasma that inhibits this amount of factor VIII is determined. If a 1:10 dilution of test plasma has this effect, the inhibitor plasma is said to contain 10 Bethesda units.

Genetic Testing

The genes encoding factors VIII and IX (*F8* and *F9*, respectively) map to the distal portion of the long arm of the X chromosome.[86,87,88,89] Therefore both hemophilia A and B are inherited as X-linked traits. Approximately two thirds of patients have a family history, while the rate of de novo mutations is approximately one in three. Genetic testing for hemophilia A and hemophilia B is now widely available.[86-88,90-92] Such testing is usually performed on the proband first, and once the mutation is identified the potential carriers of hemophilia in the family can be then tested. Prenatal testing for hemophilia is performed by amniocentesis or chorionic villus biopsy[90] and may be useful for the perinatologist and neonatologist in the management of pregnancy, delivery, and immediate neonatal care. Databases of the known mutations causing hemophilia A are available (http://hadb.org.uk). The most common genetic alteration is inversion. Gene inversion occurs in approximately 45% of patients with severe hemophilia A, with most inversions originating in male germ cells. The most common inversion occurs in intron 22 of *F8;* this inversion accounts for approximately half of the cases of severe hemophilia A.[93] In families in which the propositus has a known molecular abnormality, genetic screening and carrier detection are highly accurate. Direct DNA sequence analysis is available for families in which the results of testing for the factor VIII gene inversion are negative. Additionally, molecular genetic diagnosis can also be done by performing linkage for the affected allele if an appropriate number of family members are available. This test is clinically available (www.genetest.org). If genetic testing is uninformative or unavailable, a coagulation-based assay to detect the carrier state may also be useful[94] and is approximately 90% accurate.

In contrast to the complexity of the factor VIII gene, the factor IX gene is considerably smaller (33 versus 187 kilobases [kb]). More than 60% of factor IX gene defects are due to missense point mutations, and an identifiable defect in the gene can be found in nearly all patients[95] (http://www.factorix.org). In approximately 50% of patients with hemophilia B, a factor IX protein that is nonfunctional is produced, whereas in the other patients no factor IX protein is produced.

Fundamentals of Treatment

Knowledge of the half-life, volume of distribution, patient's inhibitor status, and appropriate replacement material is necessary to make intelligent decisions for the treatment of bleeding episodes.[96-98] Prompt and appropriate treatment of hemorrhage and prophylactic therapy are the key to excellent care of patients with hemophilia. Home therapy and prophylactic therapy have revolutionized the care of children and adults with hemophilia. Early or prophylactic treatment prevents the long-term morbidity of hemophilia. For adequate treatment of mild to moderate hemorrhage, it is necessary that factor VIII levels of 30 to 50 U/dL or factor IX levels of 30 U/dL be achieved.

For patients with mild hemophilia A who have previously shown a satisfactory response to desmopressin acetate (DDAVP, 1-deamino-8-d-arginine vasopressin), this drug is the treatment of choice for bleeding episodes of mild to moderate severity.[99-101] For life-threatening hemorrhage, the immediate aim is to correct the patient's clotting factor level to normal (100 to 150bU/dL) and to maintain a nadir level between 50 and 60 U/dL for 5 to 7 days, followed by a vigorous maintenance treatment program.

Table 31-1 summarizes the treatment of specific types of hemorrhage in hemophilia A and hemophilia B. Calculation of the dose, recommendations concerning prophylaxis, and the specific treatment products for hemophilia A and hemophilia B are reviewed later.

Hemophilia A

Calculation of Dose. Calculation of the dose required to achieve a desired hemostatic level is based on a convenient formula derived from the work of Abildgaard and colleagues[11]:

$$\text{Dose factor VIII (units)} = \text{U/dL desired rise in plasma factor VIII} \times \text{Body weight (kg)} \times 0.5$$

Thus for treatment of hemarthrosis in a 20-kg child with severe hemophilia A, to achieve a plasma level of 60 U/dL, the dose would be 60 U/dL × 20 kg × 0.5 = 600 units of factor VIII.

For patients undergoing major surgery or with serious hemorrhage, the plasma factor VIII level should be initially corrected to 100 to 150 U/dL (immediately before the procedure if given for surgery) and maintained at greater than 50 to 60 U/dL for 5 to 7 days and then at greater than 30 U/dL for an additional 5 to 7 days. This can be accomplished by infusion of intermittent doses of factor VIII based on a half-life of 12 hours (e.g., administration of 30 U/kg [60-U/dL correction] every 12 hours).

Alternatively, a level of 50 to 60 U/dL can be maintained by continuous infusion of factor VIII at a rate of 2 to 3 U/kg/hr.[102,103] The level of factor VIII should be monitored periodically to ensure that the expected levels are attained. Immediately after surgery, it is advisable to administer 25 U/kg of factor VIII concentrate to compensate for the loss of factor VIII by increased consumption and blood loss during the surgical procedure. For surgical procedures and limb- or life-threatening hemorrhage, factor VIII levels should be monitored at least every 24 hours. CNS bleeding should be treated for a 2- to 3-week course of therapy. Such patients have a risk of recurrence of CNS bleeding for approximately 6 months after an episode, and these patients often continue to receive prophylactic therapy. At the conclusion of therapy for CNS hemorrhage, CT should be performed to provide a baseline scan for comparison if any subsequent CNS symptoms appear and to demonstrate resolution of the previous hemorrhage.

For treatment of more routine bleeding episodes, such as hemarthrosis, often only one to two doses of clotting factor replacement (plasma factor VIII level of 80 to 100 U/dL), initially followed by infusions as recommended in Table 31-1, are required to produce significant clinical improvement. Nevertheless, many centers are now using a more aggressive approach to managing severe joint hemorrhage by administering follow-up infusions daily until the signs and symptoms have resolved and then every other day for 7 to 10 days to limit the potential development of chronic joint disease. For dental extractions, mouth lacerations, or recurrent epistaxis, adjuvant antifibrinolytic therapy should be used (discussed later).

Prophylactic Factor VIII Therapy. Most centers in the United States and other developed countries are now routinely giving individuals factor VIII prophylactic replacement therapy with recombinant factor VIII.[27,104,105] Most centers initiate prophylactic therapy as soon as joint bleeding occurs while others start in early life even before the first bleed occurs. This therapy is usually administered through a subcutaneous access port after the insertion of a central venous line.[106,107] Insertion of such lines is often associated with catheter infections or thrombosis (or both), so patients and family members must be aware of the signs and symptoms.[107] In general, a dose of 20 to 40 U/kg of factor VIII is administered every other day or three times a week. The dose and rate are adjusted to ensure that the nadir before the next infusion is greater than 1 U/dL. The levels attained by use of this regimen usually prevent spontaneous bleeding, although hemorrhage caused by trauma may still require additional replacement therapy. The goal is to prevent recurrent hemarthrosis and associated chronic hemophilic arthropathy and thereby promote a normal lifestyle. A number of centers throughout the world have initiated prophylactic therapy programs and have demonstrated their cost-effectiveness when productivity and lifestyle are used as indicators of success.[25,108] However, this long-term vision is not always shared by administrators of managed health care systems, and the most successful programs have been carried out in countries with nationalized health care.

Factor VIII Treatment Products. Clotting factor replacement products should be rendered as free as possible of transfusion-transmissible agents, but vigilance is still necessary. As a result, recombinant products are generally considered to be preferable to plasma-derived products. Because even recombinant products may contain human albumin added as a stabilizer, products have recently been developed that contain no human plasma–derived protein.[109,110] The question of which product to use, the rate of administration, and the potential use of prophylaxis are decisions that need to be made by the health care provider, the family, and the patient.

Recombinant Factor VIII Concentrates. The factor VIII gene has been cloned, sequenced, and used to successfully transfect mammalian cells to produce recombinant factor VIII,[111] and several recombinant factor VIII products have been licensed. Clinical trials have documented that the half-life, recovery, and efficacy of these recombinant factor VIII products are similar to those for plasma-derived factor VIII.[20,21] Advantages of these recombinant factor VIII products are their freedom from human viral contamination and their production by methods that do not require human blood or plasma donors. There was initial concern that there may be an increase in the incidence of inhibitor development in previously untreated patients, but this appears not to be warranted.[112-117] Careful study of patients receiving recombinant products identified inhibitors in 20% to 25%, as opposed to the previously reported 14% prevalence of inhibitors.[118] The difference is now thought to be due to detection of transient inhibitors that subsequently disappear and not due to differences between the immunogenicity of recombinant factor VIII and plasma-derived factor VIII. More recent studies have revived interest in this issue, and a number of studies are re-evaluating whether factor VIII in the presence of VWF might be less immunogenic.[119-122] A recombinant factor VIII product missing the B domain has been licensed, which may require a different approach to laboratory monitoring because its activity differs between one- and two-stage factor VIII assays.[123,124] More recently developed products are formulated so that other human proteins are removed.[109,110]

Plasma-Derived Factor VIII Concentrates. Several commercial plasma-derived factor VIII concentrates are available. Intermediate-purity concentrates are produced from large pools of donor plasma by a combination of cryoprecipitation or precipitation with glycine, polyethylene glycol, or ethanol.[125] These intermediate-purity products contain 2 to 5 units of factor VIII per milligram of protein. Products of higher purity have also been developed and are produced by immunopurification of factor VIII with the use of monoclonal antibodies to factor VIII[126] or VWF.[127] All these products undergo multiple purification steps that involve heat treatment, as well as other modalities, to reduce the risk of viral transmission. As a result, the risk of human immunodeficiency virus (HIV) infection; hepatitis B; hepatitis C; and, more recently, transmission of hepatitis A and parvovirus B19 has been markedly reduced or eliminated.[128-130]

With the improved purity of plasma-derived products, the incidence of complications has greatly diminished. Allergic reactions, isohemagglutinin-induced hemolytic anemia, immune complex–mediated hematuria, and granulocyte antibody–induced lung injury are rarely seen. The use of immunoaffinity-purified factor VIII concentrates and recombinant factor VIII concentrates appears to stabilize CD4$^+$ counts in HIV-infected patients with hemophilia.[131,132]

To minimize the risk for hepatitis B and hepatitis A, unimmunized patients should be immunized at the time of diagnosis.[133,134]

Cryoprecipitate. The first widely used preparation of factor VIII was made by Judith Graham Poole in 1965 by a method called cryoprecipitation.[135] Each bag of cryoprecipitate contains only 100 units of factor VIII, and thus 10 to 20 donor units are required for the treatment of joint hemorrhage in an adult. Because cryoprecipitate lacks any active method of viral inactivation, possesses significant amounts of other human proteins, and is inconvenient to administer, it is no longer considered a viable alternative to purified factor VIII products, except in areas of the world where other forms of therapy are unavailable or in short supply.

Desmopressin. Desmopressin is a synthetic vasopressin analogue that increases plasma factor VIII and VWF levels, thereby allowing successful treatment of bleeding episodes associated with dental and surgical procedures in patients with mild and moderate hemophilia A and VWD.[137] Desmopressin is now considered the treatment of choice in patients with mild and moderate hemophilia A who have shown a response to the drug during a therapeutic trial. It is not effective in the treatment of severe hemophilia A, severe VWD, or any form of hemophilia B.

The individual response to desmopressin is varied,[138] with the range of increase in factor VIII level being between twofold and fifteenfold over baseline in patients with mild or moderate hemophilia A. It is therefore recommended that patients undergo a therapeutic trial of desmopressin with laboratory measurement of response to factor VIII before it is used for the treatment of bleeding episodes or as prophylactic therapy before dental and other surgical procedures. A similar degree of response is generally seen in an individual patient with subsequent doses,[139] and thus the factor VIII level attained after a trial dose can be used to predict the response to future therapy. The level of response to factor VIII is not usually sufficient to treat life- or limb-threatening hemorrhage. Tachyphylaxis may occur with repeated doses of desmopressin, but this varies from patient to patient.[140] Consequently, if repeated doses of desmopressin are to be administered, factor VIII levels should be monitored, and if necessary, exogenous factor VIII should be administered. In general, if several days have elapsed between doses, a response similar to that for the baseline infusion can be expected. Side effects from the administration of desmopressin are minimal and include headache; flushing; a slight change in pulse rate or blood pressure; and, rarely, hyponatremia. Because hyponatremia after the administration of desmopressin may cause a seizure in rare instances, particularly in young children,[141] fluid intake should be restricted to maintenance levels for at least 24 hours. If repeated doses of the drug are given, serum sodium levels should be monitored. Because of rare reports of thrombosis after the use of desmopressin,[142] the drug should be used with caution in patients with an increased risk for thrombosis.

The recommended intravenous dose of desmopressin is 0.3 μg/kg, and it is administered in 25 to 50 mL of normal saline over a period of 20 to 30 minutes.[100] If desmopressin is being given before a procedure such as a dental extraction, it should be administered as close to the procedure as possible because the maximal response occurs 30 to 60 minutes after administration. A concentrated form of desmopressin (Stimate) is available for intranasal administration to treat bleeding disorders. This preparation should not be confused with the far less concentrated formulation (brand name DDAVP) that is used to treat enuresis; the latter formulation is ineffective for the treatment of hemophilia and VWD. The appropriate dose of intranasal Stimate is 150 μg (1 puff) for persons weighing less than 50 kg and 300 μg (1 puff in each nostril) for persons weighing more than 50 kg.[143] It is particularly important to document the response to intranasal desmopressin before it is used for the treatment of bleeding.

Antifibrinolytic Therapy. Bleeding from mucosal surfaces in patients with hemophilia is often problematic because of the increased fibrinolytic activity associated with the mucosa. Antifibrinolytic therapy has been found to be effective in controlling mucosal bleeding, especially from the oral mucosa. Although hemostasis is generally achieved with either factor VIII replacement or desmopressin, the risk of recurrent bleeding from oral mucosal surfaces is dramatically reduced with the administration of antifibrinolytic agents. Use of these agents for nasal bleeding or for bleeding from the urinary tract or gastrointestinal surfaces has not been studied extensively. The clearest demonstration of their efficacy is with dental extractions, for which transfusion therapy was previously required for 10 to 12 days. With the use of antifibrinolytic therapy, a single infusion of factor VIII and 7 to 10 days of antifibrinolytic therapy are usually sufficient to prevent recurrent hemorrhage after dental extractions.[51,144] In addition, tranexamic acid has been shown to be effective when used topically as a mouthwash.[145]

Two antifibrinolytic agents, aminocaproic acid and tranexamic acid, are available. Aminocaproic acid (Amicar) is formulated in an intravenous form, oral tablets, and an elixir.[146,147] The tablet contains 500 or 1000 mg, and the elixir contains 250 mg/mL. Because the tablets are large and the usual dose is 5 g (5 to 10 tablets), most adult patients prefer taking the elixir. The oral dose of ε-aminocaproic acid is 100 to 200 mg/kg initially (maximum dose, 10 g), followed by 50 to 100 mg/kg per dose every 6 hours (maximum dose, 5 g). The second agent, tranexamic acid, is available in 650-mg capsules (Lysteda). The dose of tranexamic acid is 25 mg/kg every 6 to 8 hours. No elixir is available for tranexamic acid. Both tranexamic acid (Cyklokapron) and aminocaproic acid are available in intravenous forms.

Treatment of Patients with Hemophilia A Who Have Inhibitory Antibodies to Factor VIII

In 14% to 25% of patients with severe hemophilia A, antibodies develop that inactivate the procoagulant activity of factor VIII; these antibodies are referred to as factor

VIII inhibitors.[112-118] The clinical hallmark of inhibitor development is failure to respond to routine replacement therapy. Patients with factor VIII inhibitors can be divided into two general categories: high responders and low responders. High responders are those in whom high-titer antibody develops with exposure to factor VIII and in whom an anamnestic response usually occurs with subsequent exposure. The titer of their antibody is in excess of 5 Bethesda units and may increase to hundreds or thousands of Bethesda units after repeat exposure. In low responders a titer of inhibitory antibody is maintained at less than 5 Bethesda units, even when they are exposed to repeated doses of factor VIII. The clinical approach is different for these two groups.

Low-Responding Factor VIII Inhibitors. Patients with inhibitor titers of less than 5 Bethesda units[148] can generally be treated with factor VIII concentrates at higher doses. Because the effect of hemophilic factor VIII inhibitor is usually time dependent, the Bethesda titer in plasma is determined after a 2-hour incubation period. As a result of this time delay, continuous administration of factor VIII is usually found to be effective.[149] For a serious limb- or life-threatening bleeding episode, a bolus infusion of 100 U/kg of factor VIII is administered, and the level is maintained by treatment at a rate of 20 U/kg/hr. An assay for factor VIII should be performed 1 hour after the bolus infusion and at least daily thereafter. As the antibody titer drops (caused by the formation of an immune complex with the high-dose factor VIII), the daily level of factor VIII may rise and thus require downward adjustment of the continuous infusion rate. For routine joint and muscle hemorrhage, patients can usually be managed[144] with infusions at twice the usual dosage. A survival study can be performed to determine the peak and half-life of the infused factor VIII. Routine inhibitor assays should be performed after exposure to factor VIII to determine whether an anamnestic response has occurred. Whether the patient remains a low responder or becomes a high responder will determine how the patient is treated for future bleeding episodes.

High-Responding Factor VIII Inhibitors. Treatment of patients with high-responding factor VIII inhibitors requires a much more aggressive approach with one of several alternative therapies. Such treatment is usually performed in sophisticated tertiary care centers by experts in the management of hemophilia.

Continuous Factor VIII Infusion. Most clinicians caring for patients with limb- or life-threatening bleeding episodes prefer to use products for which therapeutic levels can be monitored. As described earlier, continuous administration of factor VIII is often effective because of the time delay in inhibition by the antibody. An initial dose of 100 to 200 U/kg can be administered, and factor VIII levels can be determined 1 hour after initiation of continuous infusion at a rate of 20 to 40 U/kg/hr. If a factor VIII level cannot be obtained (i.e., patients with Bethesda titers greater than 5 to 10 Bethesda units), alternative approaches are usually indicated.

Porcine Factor VIII Concentrate. Because of the high degree of functional homology with human factor VIII, porcine factor VIII represents an attractive alternative for patients with hemophilia and high-responding inhibitors. Plasma-derived porcine factor VIII was a highly purified material produced by polyelectrolyte ion exchange chromatography.[150,151] In patients whose Bethesda titer was less than 50 Bethesda units, a therapeutic factor VIII level was usually attained by using this porcine factor VIII concentrate. Because of contamination with parvovirus, this plasma-derived porcine factor VIII is no longer available. Recombinant porcine factor VIII is being explored as a new therapeutic option for factor VIII inhibitor patients, but it is not yet licensed.[152]

Recombinant Factor VIIa. A recombinant factor VIIa (activated factor VII) concentrate has been developed and demonstrated to produce hemostasis in patients with high-responding inhibitors.[153,154] It is thought to interact with tissue factor and platelets at the site of vascular injury and thereby activate factor X and promote thrombin generation in a manner that bypasses the factor VIII–dependent steps.[155]

The initial dose is 90 to 120 μg/kg of factor VIIa, with additional doses administered every 2 hours. The subsequent rate of infusion and duration of therapy must then be individualized on the basis of the clinical response and severity of bleeding. Recently, the use of higher bolus doses of 180 to 270 μg/kg has been advocated to presumably establish a higher "thrombin burst" at the site of vascular injury.[156]

Prothrombin Complex Concentrate. Prothrombin complex concentrates may sometimes be used to treat routine joint and muscle hemorrhage in patients with hemophilia A and inhibitors. The exact mechanism by which the beneficial effects of these concentrates are produced is still not fully understood. A multicenter controlled study of hemarthrosis demonstrated that these concentrates promoted hemostasis in 50% of bleeding episodes. The initial dose is 75 U/kg of factor IX. If there is no response after two or three infusions given 12 hours apart, it is unlikely that additional treatments will be successful. If repeated doses of these concentrates are administered, consideration should be given to the addition of heparin owing to the potential increased risk for thrombosis.

Activated Prothrombin Complex Concentrates. There is currently one commercially available "activated" prothrombin complex concentrate, FEIBA (factor eight inhibitor–bypassing activity). This product has been purposefully activated during the fractionation process to achieve increased amounts of activated factor VII, factor X, or thrombin. Double-blind controlled trials have demonstrated that this product has small but significant advantages over standard prothrombin complex concentrates.[157] In contrast to porcine factor VIII or continuous-infusion factor VIII, these products are effective even in patients with high-titer inhibitors. The initial dose of 75 U/kg can be repeated in 6 to 12 hours. If multiple doses are administered, the patient should be monitored for the development of disseminated intravascular coagulation or even myocardial infarction, which has been reported with the use of these concentrates.[158] The simultaneous use of antifibrinolytic therapy should be avoided in these patients. If this treatment is not successful, recombinant factor VIIa treatment is usually considered.

Immune Tolerance to Factor VIII. Immune tolerance was first attempted in the 1970s and was achieved by the administration of high doses of factor VIII (100 to 150 U/kg) twice daily and the use of activated prothrombin complex concentrates for acute bleeding episodes.[159] This strategy attempts to eliminate inhibitors through administration of repetitive doses of factor VIII with or without immunosuppressive therapy. After a period of months or even years, the titer of factor VIII antibodies was markedly reduced, and the dose could be decreased to a smaller daily dose or even doses given every other day. A less aggressive approach using lower doses of factor VIII has generally been demonstrated to be less effective.[160] Proposed immune tolerance induction mechanisms include clonal deletion of antibody-producing B cells, induction of suppressor T cells, and synthesis of anti-idiotype antibodies. This approach is effective in as many as 70% of patients with hemophilia A, but much less so in hemophilia B. If bleeding occurs during immune tolerance induction, a bypass agent is used. Either activated prothrombin complexes or activated recombinant factor VIIa has been shown to be efficacious in this setting. Various reports have also described the use of intravenous gamma globulin, immunosuppressive therapy, removal of the antibody by extracorporeal immunoadsorption on *Staphylococcus* protein A columns, or a combination of these modalities.[161] Immune tolerance in four of five patients treated with porcine factor VIII on a home-based infusion program has also been reported.[162] Reports suggest that early treatment of patients with inhibitors to induce immune tolerance is more successful and that higher doses of factor VIII may allow hemophiliacs to become tolerized more rapidly.[163-165]

Hemophilia B

Calculation of Dose. Because factor IX has a volume of distribution different from that of factor VIII, the amount of plasma-derived factor IX that is required to achieve a similar plasma level is approximately twice that for factor VIII:

$$\text{Dose of factor IX (units)} = \text{U/dL (percent) desired rise} \times \text{Body weight (kg)}$$

Thus for the treatment of hemarthrosis in a 20-kg child in whom a level of 80 U/dL is desired, the dose would be 80 U/dL × 20 kg = 1600 units of factor IX.

If recombinant factor IX concentrate is used, the dose must be increased 1.2- to 1.5-fold because of the poorer recovery of recombinant factor IX.[166] Thus in the example just presented, the dose of recombinant factor IX would be 1920 to 2400 units. It is recommended that the recovery of factor IX after an infusion be established for each patient to accurately determine subsequent therapeutic doses. The half-life of factor IX (18 to 24 hours) is much longer than that of factor VIII (10 to 12 hours), and therefore factor IX does not need to be administered as often. Whereas the minimal hemostatic level of factor VIII is 30 to 40 U/dL, that of factor IX appears to be 25 to 30 U/dL.[167]

Factor IX Concentrates

Plasma-Derived Factor IX Concentrates. Hemophilia B can now be treated with highly purified factor IX products derived from plasma through purification or monoclonal immunoaffinity.[168] These highly purified factor IX concentrates are preferred over prothrombin complex concentrates for the treatment of major bleeding episodes, especially in patients with impaired liver function, massive crush injury, or a history of thrombosis. As discussed later, prothrombin complex concentrates are much more likely to be thrombogenic because of the presence of activated vitamin K–dependent clotting factors. Anaphylaxis in association with inhibitor development has been reported in patients receiving high-purity factor IX concentrates.[169,170] It is therefore usually recommended that administration of the first several doses of factor IX be observed in an emergency department where anaphylaxis can be treated if necessary.

Recombinant Factor IX Concentrates. Recombinant factor IX is considered the preferred product for treating patients with hemophilia B. As mentioned earlier, there is reduced recovery of recombinant factor IX, so 20% to 50% more factor IX must be used to achieve the same plasma concentration as plasma-derived factor IX.[171,172]

Prothrombin Complex Concentrates. The vitamin K–dependent clotting factors are of similar size and have similar biochemical and physical chemical properties. Thus fractionation procedures such as barium sulfate precipitation and column chromatography with various adsorbents purify many of the vitamin K–dependent clotting factors together.[173,174] This material is therefore called prothrombin complex concentrate. These concentrates have been found on rare occasion to cause life-threatening thrombotic complications, including deep venous thrombosis, myocardial infarction, pulmonary emboli, and disseminated intravascular coagulation.[175,176] The risk of thrombosis is increased in patients receiving high or repetitive doses, in patients with impaired fibrinolysis (liver disease or after treatment with antifibrinolytic agents), and in those with impaired ability to clear activated clotting factors (i.e., patients with liver disease). When prothrombin complex concentrates are used repetitively, especially in high doses, the International Society of Thrombosis and Hemostasis (ISTH) has recommended the addition of 100 units of heparin to each 500 units of factor IX concentrate.[177] When factor IX is replaced, this level of heparin is not a problem.

Rather than adding heparin to the prothrombin complex concentrates, most physicians currently prefer to use the more purified factor IX products or recombinant factor IX to treat patients with factor IX deficiency when high or repetitive doses are required. Factor IX concentrates and prothrombin complex concentrates have undergone dry heating or vapor heating at high temperatures to reduce the risk of HIV infection and hepatitis C.[178]

Fresh Frozen Plasma. Although fresh frozen plasma was historically used to treat hemophilia B, its use today is limited to areas of the world where factor IX concentrates are unavailable or in emergency situations when factor IX concentrates are not available. If large amounts of fresh frozen plasma are used, the plasma should be ABO blood type compatible to prevent the complication of hemolytic anemia caused by the infusion of isohemagglutinins. Patients with a normal cardiovascular system can safely tolerate a dose of 15 to 20 mL/kg.[179]

Treatment of Hemophilia B Patients with Factor IX Inhibitors

The incidence of inhibitory antibodies to factor IX is much lower than that seen with factor VIII, but these antibodies are commonly associated with the development of anaphylaxis. When such antibodies are identified, activated prothrombin complex concentrates and recombinant factor VIIa have been found to be the most successful therapies. However, the use of activated prothrombin concentrates is contraindicated in patients in whom anaphylaxis has developed along with the inhibitor because they too contain factor IX. Recombinant factor VIIa does not contain any factor IX and is therefore the preferred therapeutic approach. The induction of immune tolerance has been disappointing in patients with factor IX inhibitors. In several patients, nephrotic syndrome has developed when factor IX was given in high doses for induction of tolerance.[180,181]

Complications of Transfusion Therapy for Hemophilia A and Hemophilia B

Transfusion-transmitted infectious diseases are a complication of transfusion therapy with plasma-derived therapeutic products in patients with hemophilia A and hemophilia B. Such diseases include HIV infection, hepatitis B, hepatitis C, and hepatitis A. With the use of recombinant factor VIII and factor IX and the newer methods of viral attenuation, many of the secondary problems associated with these complications can be avoided or minimized. As discussed earlier, hepatitis B and hepatitis A vaccines should be administered to patients before or concomitant with initial therapy.

Comprehensive Care and Home Therapy

Care of patients with hemophilia requires a comprehensive team of health care providers that includes a hemophilia specialist, nurse coordinator, social worker, psychologist, physical therapist, dentist, orthopedic surgeon, financial counselor, primary care physician, and sometimes an infectious disease specialist.[182-184] This approach is considered to be the standard of care and is provided primarily through comprehensive hemophilia treatment centers. The occurrence of primary and secondary complications of hemophilia is reduced, and patient performance both at school and in the workplace is improved.[182] Additionally, overall survival appears to be significantly greater among patients with hemophilia who receive care at hemophilia treatment centers.[184]

A revolution occurred in hemophilia care with the development of factor concentrates and the potential for treatment of bleeding episodes at home. This has become the standard venue for the administration of replacement therapy for the majority of hemorrhages in patients with hemophilia. With home therapy, treatment can be administered sooner, which can reduce the long-term morbidity of hemophilia and thereby reduce the total cost of the disease. Home care programs should be monitored closely by the comprehensive hemophilia team and requires the physician, nurse coordinator, patient, and family to have a close working relationship.[185] Today many patients receive routine primary prophylactic therapy at home administered through a subcutaneous port and a central venous access line.

Future Gene Therapy for Hemophilia A and Hemophilia B

Because of the potential for a complete cure, gene therapy for hemophilia is still being actively pursued on an investigational basis. Animal models of hemophilia A and hemophilia B have been developed or maintained in dogs, mice, and sheep. Early success with gene therapy in these animal models has been achieved, but long-term maintenance of a satisfactory plasma level of clotting factor continues to be an issue. Human gene therapy trials have been carried out for both hemophilia A[187-189] and hemophilia B.[190-192] Although extensive preclinical studies have demonstrated the potential for gene therapy in hemophilia; those clinical trials were somewhat disappointing. More recently a successful trial was published in which the investigators obtained phenotypic correction with persistent expression of greater than 1% factor IX activity. The trial used an adeno-associated virus vector engineered for factor IX expression specific to the liver, resulting in factor IX expression in each of six individuals treated.[27a] New approaches include the use of gain of function factor IX variants that may increase the efficiency of the vector. Because inhibitory antibodies will develop in more than 25% of patients treated with clotting factor concentrates, it is not yet clear whether gene therapy will have a similar incidence or whether continuous release by the transgene will provide tolerance in these patients. One recent preclinical approach consists of directing factor VIII expression to platelets where the factor VIII is stored and can be released locally by platelets.[194-196,197] One group has demonstrated that this approach appears to be effective even in the presence of high-titer inhibitory antibodies.[196] Gene therapy has made significant gains in the last 10 years, but many problems remain, including selection of both appropriate vectors and the appropriate cell in which to express the gene. Control of potential deleterious side effects must still be solved.[186]

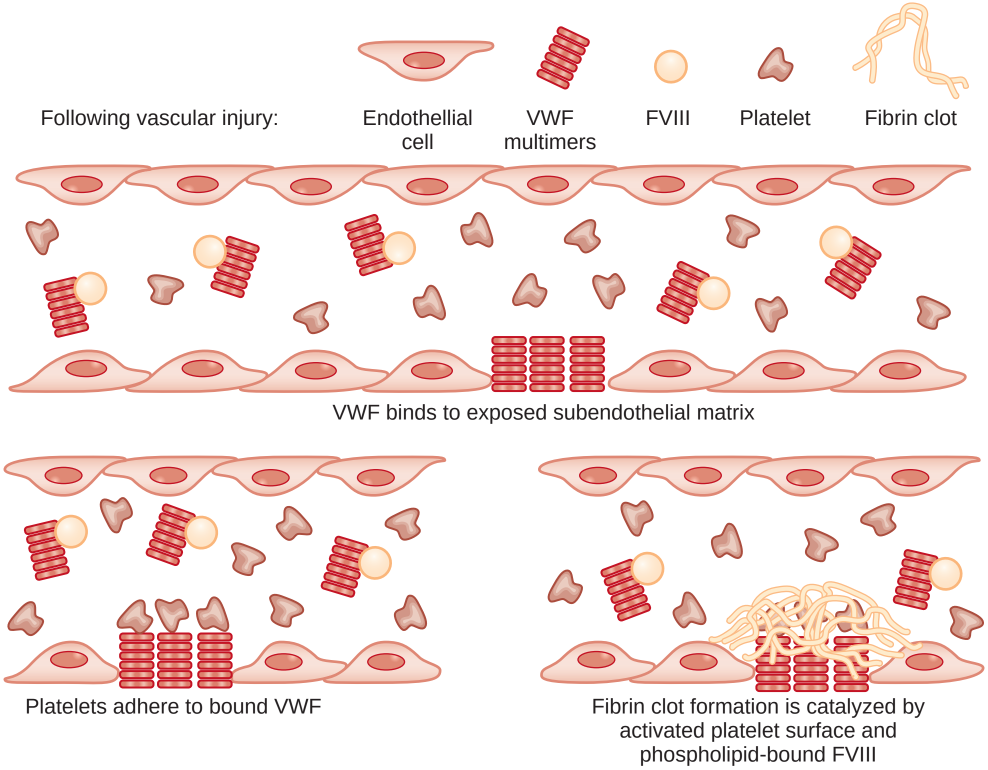
VON WILLEBRAND DISEASE

VWD is a disorder of VWF, a large multimeric glycoprotein that: (1) contributes to the adherence of platelets to damaged endothelium and (2) serves as a carrier protein for plasma factor VIII. Deficiency of VWF results in mucocutaneous and posttraumatic or postsurgical bleeding, but if VWF is absent or markedly reduced, the secondary reduction in plasma factor VIII may also result in muscle or joint bleeding similar to that seen in hemophilia A. Erik von Willebrand first described this disorder in 1925 in persons living on the Åland Islands off the coast of Finland.[198-200] VWD is a very common but heterogeneous disorder, resulting from a variety of genetic defects. These include congenital absence of VWF, mutations in which the structure or function of the molecule is markedly abnormal, and mutations associated with mild decreases in expression. Some patients have low VWF levels without a defined genetic defect. It is inherited autosomally; thus in contrast to hemophilia A and hemophilia B, the incidence of VWD in men and women is comparable, although more women may receive the diagnosis because of menorrhagia.

Pathophysiology

VWF is a large multimeric glycoprotein that is synthesized in megakaryocytes and endothelial cells and stored in specific cellular storage granules: the Weibel-Palade body in endothelial cells and the alpha granule in platelets.[201,202-204] Figure 31-1 depicts the role of VWF in localizing and facilitating the hemostatic process. After an injury to the endothelial cell wall of the blood vessel, the local concentration of VWF is increased by the interaction of VWF with components of the subendothelial matrix, such as collagen.[205] When VWF binds collagen, it changes conformation, allowing it to bind to the platelet glycoprotein Ib-IX-V complex (GPIb-IX-V) receptor, thereby resulting in adherence of circulating platelets to the site of damaged endothelium.[206,207] VWF is also capable of interacting with the $\alpha_{IIb}\beta_{III}$ (GPIIbIIIa) receptor on platelets (Chapter 26), and this action may be promoted by shear stress.[208-210] Once VWF causes the platelet to adhere by way of the GPIb-IX-V receptor complex, the platelet is activated, causing recruitment of additional platelets.[211] This is termed *platelet aggregation* and results in formation of a platelet plug (see Fig. 31-1). Formation of the platelet plug also depends on the presence of plasma fibrinogen, the primary ligand for platelet aggregation. Thus in the absence of VWF (or in the presence of VWF with abnormal structure), platelets are poorly targeted to the site of endothelial cell damage, resulting in less than optimal hemostasis.

VWF also serves as a carrier protein for plasma factor VIII and is necessary for normal recovery and survival of factor VIII.[212-214] In the absence of VWF, lack of the carrier molecule function results in a secondary deficiency of plasma factor VIII as the result of accelerated clearance.[74,215] Recombinant factor VIII is produced more efficiently within cells transfected with genes for both VWF and factor VIII.[216,217] Thus patients with severe VWD (type 3) usually have a prolonged bleeding time and prolonged PTT caused by a decrease in both VWF and factor VIII. Milder forms of this disorder can differ and are described in more detail later.



Following vascular injury:
Endothellial cell
VWF multimers
FVIII
Platelet
Fibrin clot
VWF binds to exposed subendothelial matrix
Platelets adhere to bound VWF
Fibrin clot formation is catalyzed by activated platelet surface and phospholipid-bound FVIII

Figure 31-1 After vascular injury, plasma von Willebrand factor (VWF) binds to the subendothelial matrix. Under shear stress VWF changes conformation, which enables the adherence of circulating platelets (platelet adhesion) through the glycoprotein receptor GPIb. Platelets are activated and recruit other platelets through platelet aggregation (platelet cohesion and aggregation). These activated platelets alter their surface phospholipids so that factor VIII (FVIII) binds, interacts with FIXa to activate the X-ase complex, and facilitates formation of the fibrin clot (coagulation).

Figure 31-2 Protein structure and its relationship to von Willebrand disease (VWD) variant subtype mutation location. Von Willebrand factor (VWF) contains specific domains that have been shown to have discrete functions, including (1) the interaction with factor VIII (FVIII; D' and D3), glycoprotein Ib (GPIb; A1), collagen (A1 and A3), ADAMTS-13 (A2), platelet GPIIb/IIIa (C1), and furin (D2-D'). The lower panel localizes hot spots for DNA mutations that cause VWF variants that tend to correlate with the functional domains. The variants include type 2A^1 (2A variants that fail to multimerize properly), type 2N (decreased interaction with FVIII), type 2B (increased binding to platelet GPIb), type 2M (decreased binding to GPIb but with normal VWF multimers), type 2A^2 (2A variants caused by increased spontaneous proteolysis of VWF by ADAMTS-13), abnormal binding to collagen, and type 1C (type 1 VWD variant with accelerated VWF clearance). aa, amino acid. *(Courtesy R. R. Montgomery.)*

Variant forms of VWF have been characterized in patients with type 2 VWD (discussed later) that cause reduced binding to factor VIII, reduced binding to platelets or collagen, and reduced size of VWF multimers. Each of these forms can therefore lead to abnormal hemostasis and clinical VWD.

Genetics

VWD is an autosomal disorder, but some patients exhibit a classic recessive inheritance (type 3 and type 2N VWD), whereas others exhibit dominant inheritance (type 2A and type 2B VWD).[218-220] The most common form, type 1 VWD, has variable penetrance and symptoms even within the same family.[218,221] Studies have shown that VWD may occur in as many as 1% to 2% of the general population,[222,223] but this high frequency likely does not represent true VWD (discussed later).[224-226] VWF gene defects are rare in individuals with VWF antigen (VWF:Ag) levels just below the normal range.[218,221,227,228,229]

The *VWF* gene spans 178 kb and contains 52 exons.[230,231,232] It encodes an 8.5 kb message that directs the synthesis of a 22 amino acid signal peptide and a 2791 amino acid pro-VWF monomer that is subsequently cleaved into a 741 amino acid propeptide and a 2050 amino acid mature VWF monomer. Figure 31-2 illustrates the relationship of the complementary DNA (8.5 kb) to the structural and functional regions of the VWF protein. The areas of this gene that have been found to contain clusters of genetic defects that cause similar phenotypes are illustrated and include type 2A,[235,236] type 2B,[237,238] type 2N,[74,239,240] hereditary persistence of pro-VWF,[241] and a type 1 variant of VWD with accelerated clearance of VWF (Vicenza variant or type 1C VWD).[242,243,244] These genetic defects can be identified either by sequencing segments of the gene following amplification by polymerase chain reaction (PCR) or by reverse transcription of messenger RNA from circulating platelets and sequencing the derived complementary DNA after PCR amplification.[236,239,240] Confirmation that any sequence variations found are responsible for the disease requires expression of the abnormal protein after transfection in vitro.[240]

Many laboratories are now carrying out such DNA analysis on unusual variants. Three studies of relatively large cohorts of families have identified a number of VWF mutations associated with the most common type of VWD, type 1.[218,228,245-248] A database of the mutations and polymorphisms found in the *VWF* gene has been established by the VWF Subcommittee of the International Society on Thrombosis and Haemostasis (https://grenada.lumc.nl/LOVD2/VWF/home.php), and a summary of the variant types of VWF has been published.[220] Care must be taken, however, in interpreting DNA sequencing results because polymorphisms are frequent in certain ethnic populations and may mistakenly be labeled as disease-causing mutations.[224] In the mouse extragenic causes of low VWF have been found and are the result of accelerated clearance of VWF owing to abnormal glycosylation.[251] In humans the major modifier of plasma VWF levels is the ABO blood group, because of glycosylation differences in the ABH antigens.[252,253] Additional modifiers of VWF levels or of clinical bleeding symptoms are being sought.

Low von Willebrand Factor Versus Type 1 von Willebrand Disease

Historically, a cutoff level below 2 standard deviations (SD) of normal VWF has been used to define a diagnosis of VWD. However, a 2 SD normal range leaves 2.5% of the population above that range and 2.5% below that range. Some studies suggest that VWD is present in 1% to 2% of the general population.[222,223] The diagnosis of mild type 1 VWD has been challenged on the basis of the argument that the plasma level of VWF is a continuous variable and may be a risk factor for bleeding rather than a defined disease state.[224,225,254] Guidelines have been published by the National Institutes of Health (www.nhlbi.nih.gov/guidelines/vwd) in which the suggested level for the designation of type 1 VWD was a VWF:Ag or VWF:RCo level of less than 30 IU/dL. Patients with bleeding and VWF levels below the normal range may still benefit from therapy such as desmopressin to raise the level of plasma VWF, even if their level is greater than 30 IU/dL. Controversy remains surrounding this issue, and many clinicians still use the term “mild type 1 VWD” to refer to individuals with VWF:Ag levels between 30 and 50 IU/dL. Low VWF or even clinical bleeding symptoms are not always associated with a clearly identifiable VWF gene mutation. Conversely, not all patients inheriting a VWF gene mutation will manifest bleeding symptoms (incomplete penetrance),[255,256] and among those who do bleed, severity can vary widely (variable expressivity).[218,246,257] Alternatively, low VWF or clinical bleeding symptoms in the absence of a VWF gene mutation may result from the effects of mutations in another gene or genes (locus heterogeneity). Research is still necessary to characterize these complex genetic factors in greater detail.

Demographics and Classification

In theory, males and females should have a similar prevalence of VWD, but diagnosis is more common in teenage and adult female subjects because of the frequent complication of menorrhagia. VWD occurs in all racial groups, although localized pockets with a very high incidence of VWF do exist, such as those in the Åland Islands of Finland and areas of Sweden, Israel, and Iran.[258-260] African-Americans have been shown to have higher levels of plasma VWF:Ag, but their VWF activity is not similarly increased.[261,262]

VWD has numerous subtypes that can be defined by structural, functional, and molecular genetic techniques. It is often categorized by quantitative or qualitative defects. Type 1 is characterized by partial deficiency of VWF and type 3 by complete absence of VWF. Type 2 variants are defined by qualitative defects. Of patients with VWD 65% to 80% have type 1 VWD, characterized by a parallel reduction in both VWF antigen and VWF activity as measured by the ristocetin cofactor activity assay (VWF:RCo).[263-265] The second most common variant is type 2A WD, in which the multimeric structure of VWF is altered such that only the smallest VWF multimers are present in plasma. This results in a marked reduction in VWF:RCo with a somewhat milder reduction in VWF:Ag.[266,267] Figure 31-3 summarizes the more common variants of VWD and their relative prevalence. Descriptions of the other VWF variants are provided in subsequent sections. Figures 31-4 and 31-5 depict the mechanisms for disease for the different types of VWD and their correlation with laboratory assays.

Clinical Screening Using Bleeding Assessment Tools

Several recent studies have focused on the clinical symptoms associated with VWD and have attempted to quantify these symptoms in the hopes of improving the specificity of the diagnosis. These scoring systems evaluated epistaxis, skin bleeding, oral or dental bleeding, gastrointestinal bleeding, muscle or joint bleeding, and CNS bleeding.[268,269] The original scoring system was modified to give weight to surgical, dental, or delivery procedures that were not treated and did not result in excessive bleeding. Modified versions have been developed for use in children, but concerns remain given that children have had less time to develop symptoms and fewer exposures to hemostatic challenges than adults.[270]

Laboratory Evaluation

Laboratory evaluation of VWD often requires multiple assays to quantitate VWD and characterize its function and structure. VWD cannot be ruled out on the basis of a normal PTT, a normal bleeding time, or a platelet function analyzer such as the PFA-100.[271,272] Therefore specific assays for VWF are required for diagnosis of VWD in patients with a history of significant bleeding.

von Willebrand Factor Antigen

Presence of the VWF protein (VWF:Ag) can be measured by a variety of quantitative immunoassays. The most widely used is the enzyme-linked immunosorbent assay (ELISA).[273-275] The World Health Organization (WHO) and ISTH have established standards for these assays and recommend reporting of results in international units standardized by the WHO.[277]

Ristocetin Cofactor Activity Assay

The activity of VWF is most commonly measured in vitro with the antibiotic ristocetin (VWF:RCo).[264,265] Ristocetin induces binding of VWF to the GPIb receptor on platelets.[208] Large multimers of VWF have more VWF:RCo activity than do the intermediate and small VWF multimers. Some laboratories perform ristocetin-induced platelet aggregation, which is a measure of both binding of VWF to the GPIb receptor and the ability of this binding to induce aggregation. This test is not nearly as sensitive as

the ristocetin cofactor assay and should not be used to rule out the diagnosis of VWD. Various methods have been developed to automate the VWF:RCo.[278-280] Because ristocetin is a nonphysiologic agonist, a number of alternative assays attempt to use shear as the stimulus for platelet binding, but to date VWF:RCo remains the most widely used assay for VWF function. Newer assays for ristocetin cofactor are being developed that use bound GPIb in an ELISA format either with or without ristocetin.[281-284] The VWF:RCo is also affected by *VWF* sequence variations such as the A1 domain polymorphism D1472H that may affect VWF binding to ristocetin without decreasing in vivo function.[285]

Low-Dose Ristocetin-Induced Platelet Aggregation

One specific use for the low-dose ristocetin-induced platelet aggregation (LD-RIPA) assay is to diagnose the hyperresponsiveness of VWF with platelets in either type 2B

VWD or platelet-type, pseudo-VWD (see Fig. 31-3).[286] These variants are important to differentiate appropriately because their response to the administration of desmopressin may be suboptimal. Each variant requires specific treatment to correct the qualitative abnormality, with VWF concentrates usually used for type 2B VWD and platelet transfusion for platelet-type, pseudo-VWD.

Collagen-Binding Assay

Assays have been developed to measure the binding of plasma VWF to collagen. In general, large multimers of VWF bind preferentially, although the type of collagen used may affect this specificity. Some have advocated replacement of the VWF:RCo assay with a collagen-binding assay (VWF:CB),[287] but the two assays measure different activities—one with platelets and the other with subendothelial matrix collagen. A few families have been identified who lack binding of VWF to collagen, with mutations located in the VWF A3 domain.[288-290] Some patients with type 2M VWD will show low binding in ristocetin cofactor assays but normal results with collagen-binding assays.[291,292] Most collagen-binding assays use type 1 collagen or type 3 collagen, although a combination of the two may provide the most sensitive results.[293] Recently, collagen binding with type 6 collagen has been described and may identify different defects than assays that use type 1 or type 3 collagen.[294]

von Willebrand Factor Multimers

VWF is present in plasma in multimers ranging from dimers of approximately 600,000 daltons to very large multimers of up to 20 million daltons.[267] The full range of VWF multimers is best demonstrated through the use of low concentrations of agarose (0.65%) and staining the multimers with radiolabeled antibody to VWF. The multimers are visualized by luminography.[266,293] Quantitative assays for multimer distribution are under development.[296] Figure 31-6 demonstrates the multimers in type 1 VWD, as well as in type 2A, type 2B, and type 3 VWD. Acquired alteration of VWF multimers may also occur in various clinical disorders, with the loss of high-molecular-weight multimers seen in patients with disseminated intravascular coagulation or ventricular septal defects.[297] Larger than normal multimers can be identified in patients with recurrent thrombotic thrombocytopenic purpura (Chapter 34).[298] Because multimer assays are technically

Figure 31-6 Multimeric analysis of von Willebrand factor (VWF) with low (0.65%) and high (3%) concentrations of agarose. Representative samples are compared and demonstrate that the low-agarose gels are preferable for detecting the loss of high-molecular-weight multimers, as seen in some VWF variants, and the increased size of VWF multimers seen in patients with thrombotic thrombocytopenic purpura (TTP). The gels with higher agarose concentration *(left)* demonstrate that single multimer bands *(left)* can be resolved into multiple satellite bands that may be selectively increased in plasma from patients with variant forms of VWD. *NP,* Normal plasma.

difficult, they are usually performed only at specialized centers.

von Willebrand Factor Propeptide

A number of laboratories now offer quantitation of the VWF propeptide (VWFpp). Because this 741-amino acid propeptide of VWF is synthesized on a 1 : 1 basis with VWF monomer, quantitation of this protein is useful in characterizing clinical states in which VWF has accelerated clearance by identifying individuals whose plasma VWFpp/VWF:Ag ratio is markedly elevated.[235,299] This is possible because the accelerated clearance affects only the VWF:Ag level and not the VWFpp level. This ratio is also markedly elevated in acquired VWD associated with an autoantibody that promotes rapid clearance of VWF.[300] Quantitation of VWFpp and VWF:Ag has also been suggested as a marker to differentiate acute and chronic endothelial perturbation.[301]

VWF Gene Sequencing

Identification of mutations or sequence variations in *VWF* is now possible with gene sequencing, either of the whole *VWF* coding sequence or select regions, such as exon 28. The diagnosis of VWD may be confirmed when well-characterized mutations are found. However, the high frequency of benign sequence variations, particularly in certain ethnic groups, makes the routine use of sequence data more challenging.[224]

Other Assays to Define Variants of von Willebrand Disease

Several additional assays are available at specialized centers to help classify variant forms of VWD. In type 2B VWD, the VWF spontaneously binds to platelets in the presence of low-dose ristocetin. Measurement of this interaction is performed with the type 2B platelet-binding assay.[239,302] In type 2N VWD, VWF has reduced affinity for factor VIII, which is best studied with a type 2N VWF factor VIII-binding assay.[240,303] The VWF:RCo/VWF:Ag ratio has been studied and helps identify patients with type 2M VWD.[291] These assays are depicted in Figure 31-7.

Variables That Affect Laboratory Assays for von Willebrand Factor

A large number of preinstrument variables may affect the determination of VWF. Standardization of assays for VWF has only recently been initiated, and a number of clinical reference plasma samples may have altered ratios of VWF antigen to activity, as well as loss of the high-molecular-weight multimers. Therefore it is imperative that each laboratory establishes its own normal range and performs careful quality control. Alternatively, samples can be sent to laboratories that specialize in VWF testing. When frozen samples are shipped, meticulous attention must be paid to the presence of contaminating platelets in the frozen plasma. If plasma is centrifuged only at 1500*g* for 5 to 10 minutes, the residual platelet count may be as high as 30,000 to 40,000/mL. When this plasma containing platelets is frozen, platelet proteases are released that alter the multimeric structure of VWF and result in an increase in the apparent amount of VWF antigen and a decrease in the VWF activity.[304] Furthermore, refrigeration of samples of whole blood before separation of plasma at a central reference laboratory may result in reducing the amount of VWF in the plasma to be tested.[305]

Clinical Disorders That Affect Assays for von Willebrand Factor

A variety of clinical disorders may affect the level of VWF. VWF behaves as an acute phase reactant protein.[306-308] Its level is markedly elevated in collagen vascular disorders, after surgery, in pregnancy, and in conditions associated with marked endothelial stimulation, such as intravascular clotting or liver disease. The VWF level is reduced in hypothyroidism and increased in hyperthyroidism.[309-312] In hypothyroidism VWF levels as low as 15 to 20 IU/dL have been observed and therefore may be associated with clinical bleeding. The multimeric structure of plasma VWF from patients with dissenminated intravascular coagulation, thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome, or ventricular septal defects may be altered with the loss or gain of high-molecular-weight multimers.

Pregnancy and even the clinical stress of a difficult phlebotomy, especially in anxious young children, may double or triple the level of VWF, thus making it impossible to rule out VWD without repeated testing. The stress of normal vaginal delivery has a marked stimulatory effect on levels of VWF in newborns,[313,314] hence making it difficult to rule out VWD in the neonatal period.

Clinical Manifestations and Medical History

The clinical manifestations of VWD are primarily epistaxis, ecchymoses, menorrhagia, and postoperative or postpartum bleeding. Because this disorder is often mild, the initial manifestation may be bleeding after surgery such as tonsillectomy and adenoidectomy. It is rare to find hemarthrosis in VWD except in patients with severe (type 3) disease. In eliciting the patient's clinical history, it is important to determine whether the size and distribution of ecchymoses are proportional to the severity of the initiating trauma. Because both bruising and epistaxis are moderately common complaints in children and are usually a result of normal childhood trauma, identification of either severe recurrent epistaxis or bruising in unusual places (back and shoulders, upper part of the arms, and thighs) may be more suggestive of a hereditary bleeding disorder. In a normal active child, minor trauma to the anterior tibial region or the forearm may result in small ecchymoses. Recurrent epistaxis is a common complaint in childhood, but in an older child or adult it is an unusual symptom that may require further evaluation. Occasionally patients with VWD have petechiae, although petechiae are more commonly associated with mild platelet function defects.

A careful family history may identify symptoms in the parents or a sibling that are similar to the patient's. The presence of recurrent epistaxis and excessive bruising in an adult is more often abnormal and suggestive of a familial bleeding disorder. The clinician should determine whether either of the parents has experienced

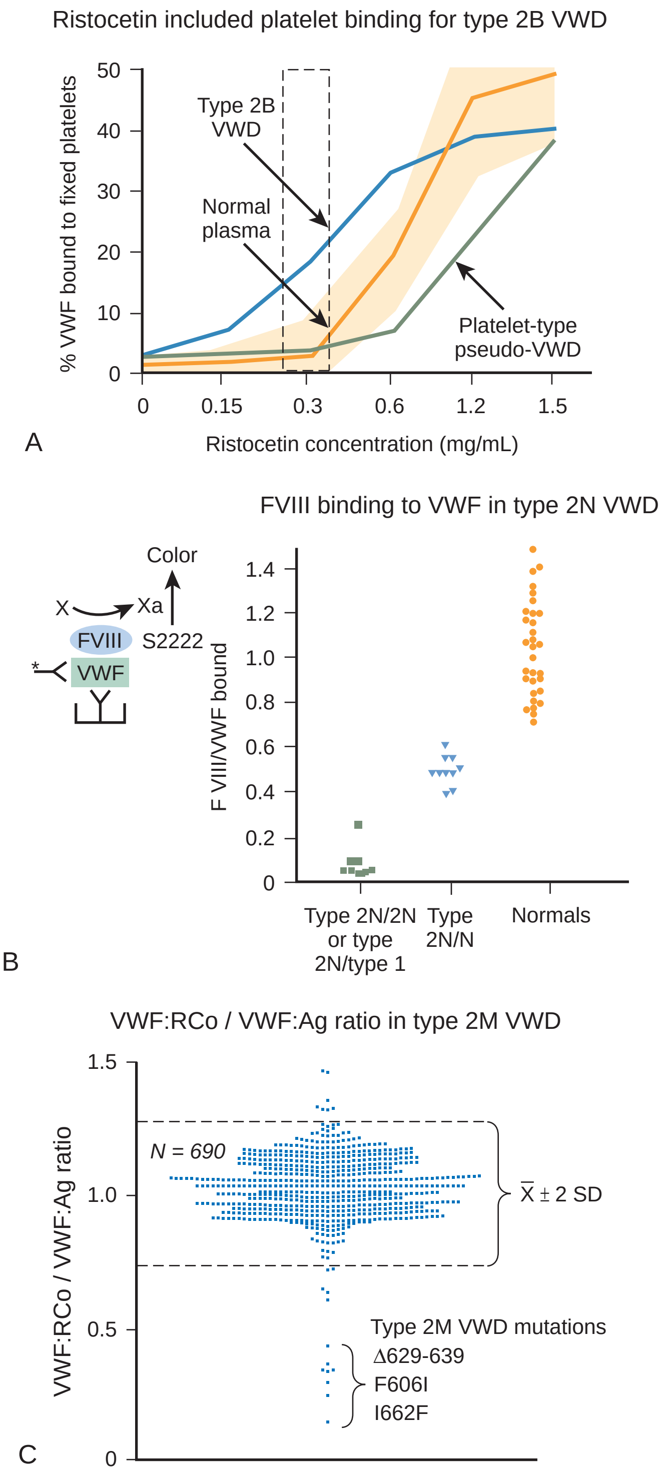

Figure 31-7 Variant forms of von Willebrand disease (VWD) can be identified by specialized phenotypic assays of patient plasma. **A,** A noninhibitory, radiolabeled antibody is added to patient plasma, and binding to normal formalin-fixed platelets is determined with various concentrations of ristocetin. At a low concentration of ristocetin (0.3 mg/mL), normal von Willebrand factor (VWF) does not bind, but type 2B VWF exhibits increased binding that is due to a shift of the dose-response curve to the left. In contrast, plasma from a patient with platelet-type pseudo-VWD shifts to the right. Thus if platelet aggregation with platelet-rich plasma (PRP) exhibits increased aggregation to low-dose ristocetin, type 2B VWD can be clearly differentiated from platelet-type pseudo-VWD with this dose-response curve. **B,** Patient VWF is bound to a microtiter well with a monoclonal antibody to VWF after patient factor VIII (FVIII) is removed. Recombinant FVIII is added and the activity of the bound FVIII determined by chromogenic (S2222) assay. The ratio of bound FVIII to captured VWF:Ag is determined and identifies heterozygous type 2N VWF (usually asymptomatic) and type 2N patients with absent FVIII binding (homozygous or compound heterozygous with a 2N allele and a "VWF-null" mutation allele). **C,** Ristocetin cofactor–antigen (VWF:RCo/VWF:Ag) ratio in a large group of patients evaluated with low-normal or abnormally low VWF levels. The ratios of eight patients with type 2M VWD are clearly below 2 standard deviations of normal, and each of these patients has an identified point mutation (F1379I or I1425F) or a deletion (?1392-1402) in the A1 domain of VWF. Patients with ratios below 0.7 and normal VWF multimers are considered to have type 2M VWD.

postoperative bleeding after major surgery, particularly tonsillectomy. Because VWD is often mild and some families learn to accept increased bruising as the norm in their family, they may not seek medical attention until bleeding occurs in the postoperative state after routine surgery or dental extraction. In teenagers epistaxis or menorrhagia, when excessive, will sometimes lead to iron-deficiency anemia; therefore, iron deficiency, particularly in menstruating teenage girls, may trigger evaluation for the presence of VWD. In a patient with severe (type 3) VWD, profuse epistaxis may occur and even result in shock,[315] although replacement therapy is generally needed less often in patients with type 3 VWD than in patients with hemophilia. In rare instances, VWD has been reported in association with congenital hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome); telangiectases should be sought in a patient with recurrent epistaxis or significant gastrointestinal bleeding.[237,316,317] Gastrointestinal blood loss in VWD may result from either occult or overt bleeding. Although bleeding may be associated with telangiectasia, usually no such anatomic cause can be determined. Such gastrointestinal bleeding may be more common in elderly patients with VWD than in children.

In patients with mild VWD, the stress associated with certain operations (e.g., ruptured appendix) may minimize clinical bleeding symptoms, whereas relatively minor surgery, such as cosmetic or mucosal surgery, may induce a major hemorrhage in a nonstressed individual.

Von Willebrand Disease Classification

Type 1 von Willebrand Disease. Type 1 VWD is the most common variant (70% to 80% of all occurrences of VWD). Type 1 VWD is generally caused by the heterozygous deficiency of VWF. The VWF produced is structurally normal, but its concentration is reduced. Most patients have levels of VWF antigen and ristocetin cofactor activity between 20 and 40 IU/dL. Patients with mild deficiencies of VWF generally do not experience spontaneous hemorrhage unless it is provoked by a major injury, surgical procedure, or dental extraction. Patients with VWF:Ag less than 20 to 30 IU/dL are more likely to have a genetic mutation in VWF than those with higher VWF:Ag levels.[218,228] Intracellular retention and increased clearance have been demonstrated as the mechanism causing low VWF levels for a select group of type 1 VWD mutations.[318,319] A gene deletion involving exons 4-5 has also been demonstrated in type 1 and type 3 VWD.[320] Type 1 VWD is characterized by a proportional decrease in VWF antigen and activity.

Type 1C or the Vicenza Variant of von Willebrand disease. Within the type 1 VWD group are individuals with accelerated clearance of their VWF who usually have plasma VWF:Ag and VWF:RCo levels below 12 to 20 IU/L and factor VIII below 30 IU/dL. The initial prototype for this disorder was termed the *Vicenza variant* because of a number of families who were identified in Italy and subsequently shown to have a common mutation (R1205H in the VWF D3 domain).[244,321,322] These patients have also been shown to have larger than normal VWF multimers and normal levels of platelet VWF. Recently, four additional families were identified with this phenotype and different mutations in the D3 and D4 domains (W1144G and S2179F).[235] This group is now referred to collectively as *type 1C* because its members have type 1 laboratory results secondary to increased clearance of VWF.[235,299] VWF synthesis in type 1C is normal. When desmopressin is administered, patients exhibit hyperresponsiveness, and their plasma VWF will increase fivefold to tenfold, but the half-life is 2 to 3 hours rather than the normal 10 to 14 hours.[235,323] Furthermore, the half-life of factor VIII released by desmopressin is similarly accelerated.[235] Infused VWF and factor VIIII have a normal half-life. Thus treatment with desmopressin will normalize the plasma concentration of VWF and factor VIII, but not for the normal time period. Minor bleeding can be treated with desmopressin, but major bleeding or surgery may require VWF concentrates to maintain the level of VWF activity and FVIII in the normal range. In this group assays of VWFpp versus VWF:Ag are diagnostically elevated in patient plasma, reflecting the accelerated clearance of VWF:Ag, but not VWFpp.[235] Type 1C VWD is characterized by an elevated VWF propeptide to antigen ratio.

Type 3 von Willebrand Disease. Type 3 VWD is usually due to autosomal recessive or compound (double) heterozygous inheritance of a null VWF allele. Thus the level of plasma VWF is usually undetectable, and the factor VIII level is generally less than 6 IU/dL. This plasma level of factor VIII is the steady-state level in the absence of its carrier protein VWF. Patients with type 3 VWD may have spontaneous bleeding, including profound epistaxis; subcutaneous hemorrhage; or, rarely, joint bleeding, as seen in patients with hemophilia.[324,325]

Type 2 Variant Types of von Willebrand Disease

Type 2A von Willebrand Disease. In type 2A VWD, there is a loss of intermediate- and high-molecular-weight multimers as a result of two different mechanisms. These were defined in the first molecular report of VWF mutations in this variant form of VWD.[356] One group is characterized by failure to synthesize intermediate- and high-molecular weight VWF multimers (referred to as type 2A[1] in Fig. 31-2); in the other group, full-length VWF is synthesized, stored, and released, but the VWF undergoes rapid proteolysis by ADAMTS-13 (referred to as type 2A[2] in Fig. 31-2).[326] Bleeding in type 2A VWD is typically more severe than that seen in either type 1 or type 2M VWD, with an observed increase in gastrointestinal bleeding as well as other mucosal bleeding.[327] Type 2A VWD is characterized by low VWF activity and a VWF:RCo/VWF:Ag ratio less than 0.7 along with loss of high molecular weight multimers.

Type 2B von Willebrand Disease. Type 2B VWD is due to a mutant VWF molecule that binds sponatenously to platelets under physiologic shear. This results in clearance of the highest-molecular-weight multimers and usually mild thrombocytopenia.[238,239,328-330] The thrombocytopenia is caused by spontaneous agglutination and clearance of platelets as a consequence of the abnormal VWF and results in loss of the high-molecular-weight multimers. Stress, pregnancy, or surgery can trigger increased levels of VWF with resultant increased agglutination of platelets and enhanced thrombocytopenia.[331,332] Thrombocytopenia is not always present, necessitating careful consideration of the diagnosis.[333] Type 2B VWD is characterized by low VWF activity and a VWF:RCo/VWF:Ag ratio less than 0.7 along with loss of high molecular weight multimers and spontaneous binding to platelets by either direct binding or increased aggregation with low-dose ristocetin, as detailed later.

Type 2N von Willebrand Disease. Type 2N VWD is the result of an abnormal VWF molecular with reduced binding of factor VIII.[74,334,335] This leads to accelerated clearance of the unbound factor VIII and a resultant reduction in plasma factor VIII as compared with the level of VWF.[336] In fact, some type 2N VWD patients may be misdiagnosed as having mild hemophilia A. It appears that the phenotype is clinically expressed only in the presence of a second allele carrying a *null* mutation or a second type 2N VWD allele (see Fig. 31-5). Misdiagnosis of type 2N VWD as mild factor VIII deficiency has been reported and will result in improper treatment of bleeding episodes.[337] Therefore if the plasma VWF level is reduced modestly and the factor VIII level is even more reduced, or if a patient with mild hemophilia A is given factor VIII and the half-life is markedly shortened, type 2N VWD should be considered. For diagnosis of type 2N VWD, a specific assay has been developed in which the patient's VWF is captured with a monoclonal antibody in a microtiter well, factor VIIII is removed by changes in pH or salt concentration or the addition of thrombin, and binding of recombinant factor VIII is determined. Type 2N VWD is characterized by low factor VIII activity and abnormal binding of VWF to factor VIII.

Type 2M von Willebrand Disease. Type 2M VWD is the result of a mutation in VWF that decreases the interaction of VWF with the platelet GPIb receptor, the converse of the effect of type 2B VWD, and also resulting in reduced VWF:RCo.[290,291,338,339] Similar to type 2A VWD, plasma VWF exhibits discordance between VWF:Ag and VWF:RCo (See Fig. 31-3), but patients with type 2M VWD have normal VWF multimers, whereas those with type 2A VWD have abnormal multimers. If the VWF:Ag and VWF:RCo assays are carefully standardized, the ratio of VWF:RCo to VWF:Ag may be used to diagnose type 2M VWD. In this variant the VWF protein can be released by desmopressin, but the released VWF exhibits abnormal interaction with platelets. Thus for major bleeding episodes or in preparation for surgery, replacement therapy with VWF concentrates should be given. Studies of type 1 VWD in two large cohorts identified some patients with mild type 2M VWD,[218,227,340] but whether clinical treatment is different in these patients will require additional study. Type 2M VWD is characterized by low VWF activity and a VWF:RCo/VWF:Ag ratio less than 0.7 with a normal multimer distribution. Mutations in the VWF gene are much more likely in patients with a VWF:RCo/VWF:Ag ratio less than 0.4.[341] Patients with mutations that affect collagen bindings are currently also classified as type 2M VWD.

Figure 31-8 depicts a simplified algorithm for the stepwise diagnosis of the different types of VWD based on laboratory data, in patients in whom there is a high index of suspicion based on personal history of mucocutaneous bleeding.

Fundamentals of Treatment

Appropriate treatment of VWD requires a specific diagnostic laboratory workup and correct classification of the type of VWF deficiency. If the patient produces normal VWF but its concentration is reduced, the plasma level can usually be increased by administering desmopressin, which induces release of VWF from endothelial storage sites into plasma.[136] If the protein that is present is abnormal, mild bleeding episodes might still be resolved with increased concentrations of the "abnormal" VWF (induced by desmopressin), but severe bleeding episodes may require the administration of normal VWF from plasma-derived products. Cryoprecipitate contains substantial levels of VWF but is not used regularly because of the lack of viral attenuation treatment. The use of cryoprecipitate is reserved for areas of the world where VWF-containing concentrates are not available.

Desmopressin

The dose of desmopressin is 0.3 µg/kg of body weight administered intravenously over a period of 20 to 30 minutes. This represents the most effective route of administration. Alternatively, subcutaneous injections of desmopressin at approximately the same dose have been used effectively.[342] Stimate (1.5 mg/mL desmopressin) is a concentrated form of desmopressin that has been shown to be effective intranasally.[343,344] The dose in teenagers and adults is 2 sprays, given as 1 spray (150 µg) in each nostril for a total dose of 300 µg. Children weighing less than 50 kg should receive 1 spray (150 µg). For the drug to be effective, the child should be old enough to cooperate with administration. The clinician should be aware that a diluted intranasal solution of desmopressin (100 µg/mL) is available for patients with diabetes insipidus and enuresis. This latter dilute form is ineffective in patients with bleeding disorders. Clinicians should also be aware of the risk of hyponatremia and seizures in patients receiving desmopressin and consider monitoring sodium levels, particularly in high-risk patients.

Although one or two doses of desmopressin combined with either aminocaproic acid or tranexamic acid (see earlier discussion under hemophilia A) is generally effective for dental extractions, major surgery usually requires maintenance of increased levels of VWF and factor VIII until healing has occurred. For most patients repeated infusions of desmopressin at 12- to 24-hour intervals are effective, but tachyphylaxis may develop.[140,345] Thus preinfusion and 30- to 60-minute postinfusion measurements of either VWF:RCo or VWF:Ag should be performed to establish the continued clinical responsiveness of the patient to desmopressin if used repeatedly. If a patient with type 1 VWD has a very low level of VWF (<20 IU/dL) and is to undergo major surgery, the levels achieved after desmopressin may be insufficient even though a twofold increase is achieved. Such patients, like those who either show no response to desmopressin or

have tachyphylaxis, must be treated with plasma-derived VWF/factor VIII.

Von Willebrand Factor Concentrates

The current Food and Drug Administration (FDA)-licensed products that contain both VWF and factor VIII for the treatment of VWD are Humate-P, Alphanate, and Wilate. Clinical trials have demonstrated their efficacy in the cessation of bleeding in patients with VWD.[346-349] Studies have compared these and other products for VWF and factor VIII content, as well as for VWF multimer content.[219] In these comparative studies Humate-P usually has the larger forms of VWF multimers, similar to normal plasma. The products also differ in their relative concentration of factor VIII, with Humate-P containing approximately 0.5 IU factor VIII per IU VWF:RCo and Alphanate containing 2.0 IU factor VIII per IU VWF:RCo. Currently Humate-P is approved by the FDA for surgery and urgent bleeding in patients with types 1, 2, and 3 VWD, and Alphanate is approved for surgery in patients with types 1 and 2 VWD. Wilate is the most recent VWF concentrate to obtain FDA approval for treatment of bleeding in all types of VWD. It contains a 1 : 1 ratio of FVIII and VWF.[350] Other intermediate purity factor VIII and VWF concentrates are sometimes used off-label, but such use is not currently recommended.

The dose of VWF concentrate is calculated as follows:

$$\text{Dose of VWF : RCo} = \text{IU/dL (percent) desired rise in plasma VWF} \times \text{body weight (kg)} \times 0.75.$$

One unit per kg of body weight of VWF will increase the plasma VWF level by 1.5 IU/dL. In preparing a patient for surgery, the clinician usually tries to correct the plasma level to approximately 100 IU/dL; plasma levels should be maintained at greater than 50 to 60 IU/dL for 3 to 7 days after major surgery. For dental extractions or minor surgery, such as repair of a laceration, the patient can generally be treated with one or two infusions of VWF concentrate along with antifibrinolytic therapy.

In Europe a concentrate containing very little factor VIII is approved, but these products are not available in the United States.[351-355] Because synthesis of factor VIII is normal in a type 3 VWD patient, providing VWF alone prevents the problems of elevated factor VIII in patients treated with factor VIII–containing VWF concentrates.[356,357] Figure 31-9 illustrates the delayed rise in endogenous factor VIII when a patient with severe type 3 VWD is administered a concentrate primilary containing VWF.

Type-Specific Treatment of von Willebrand Disease

For type 1 VWD patients, the safest therapy is to augment the patient's plasma VWF concentration by stimulating the endogenous release of VWF with desmopressin, as described earlier.[136] More than 90% of patients with type 1 VWD have a twofold to fourfold increase in their plasma levels of VWF (Fig. 31-10) and factor VIII within 15 to 30 minutes of infusion, with the same half-life as transfused VWF or factor VIII (approximately 12 hours). Occasionally, patients are encountered who do not mount an adequate response to the infusion of desmopressin. This is particularly true for children younger than 1 to 1½ years of age, who may exhibit a diminished response or symptoms of hyponatremia, or both.[141] It is usually recommended that patients in whom VWD is diagnosed be given a therapeutic trial of desmopressin to determine their responsiveness to the drug so that when future therapy is required, the clinician knows that this form of treatment will be effective.

For type 3 VWD patients, administration of desmopressin is not effective because their cells do not contain endogenous VWF and the desmopressin-induced release of factor VIII is dependent on endogenous synthesis of VWD.[215] Sometimes a therapeutic trial of desmopressin in these patients is worthwhile because it might identify patients with type 1C who have VWF:Ag levels below the detection limit in some laboratories.[323] In patients with undetectable VWF or an inadequate response to desmopressin, bleeding symptoms must be managed with plasma-derived VWF or factor VIII/VWF concentrates. Management is similar to that for patients with severe hemophilia and consists of factor VIII concentrates that contain normal or nearly normal VWF. Survival of the transfused VWF is virtually identical to that for factor VIII (discussed earlier). Levels similar to those used for treatment of hemophilia, both preoperatively and postoperatively, should be maintained for adequate hemostasis. Because the licensed concentrates have different ratios of factor VIII to VWF, care must be exercised to ensure adequate factor VIII levels with the first infusion and to avoid excessively high factor VIII levels after several days of intensive or postsurgical treatment.[358]

A number of centers are now using prophylaxis to prevent bleeding in type 3 VWD patients if clinically indicated because of the amount or severity of recurrent bleeding.[359-362] Since the half-lives of VWF and factor VIIII are comparable, the approach is similar to that used in hemophilia A (factor VIII deficiency). In patients with type 3 VWD and large gene deletions, there is an increased likelihood of antibody development.[363,364] Recombinant factor VIIa has been reported to be effective in some patients with severe VWD and alloantibodies.[365-367]

For type 2A VWD patients, if desmopressin is administered, the correction of VWF multimers is transient, and the bleeding time may or may not shorten.[368] Therefore patients with type 2A VWD may require treatment with plasma-derived VWF/factor VIII concentrate containing normal VWF multimers (see earlier). It may be possible to treat minor bleeding episodes and bleeding after dental extractions with desmopressin, which gives a brief increase in plasma levels of VWF. A trial of desmopressin and measurement of in vitro survival of VWF:RCo are required to determine potential efficacy.

For type 2B VWD patients, although one might assume that desmopressin would not be efficacious, studies have demonstrated its effectiveness in some patients.[369,370] Therefore for mild bleeding a trial of desmopressin can be initiated and the platelet count and bleeding monitored. For internal bleeding or major surgery, administration of VWF/factor VIII concentrate is generally required.

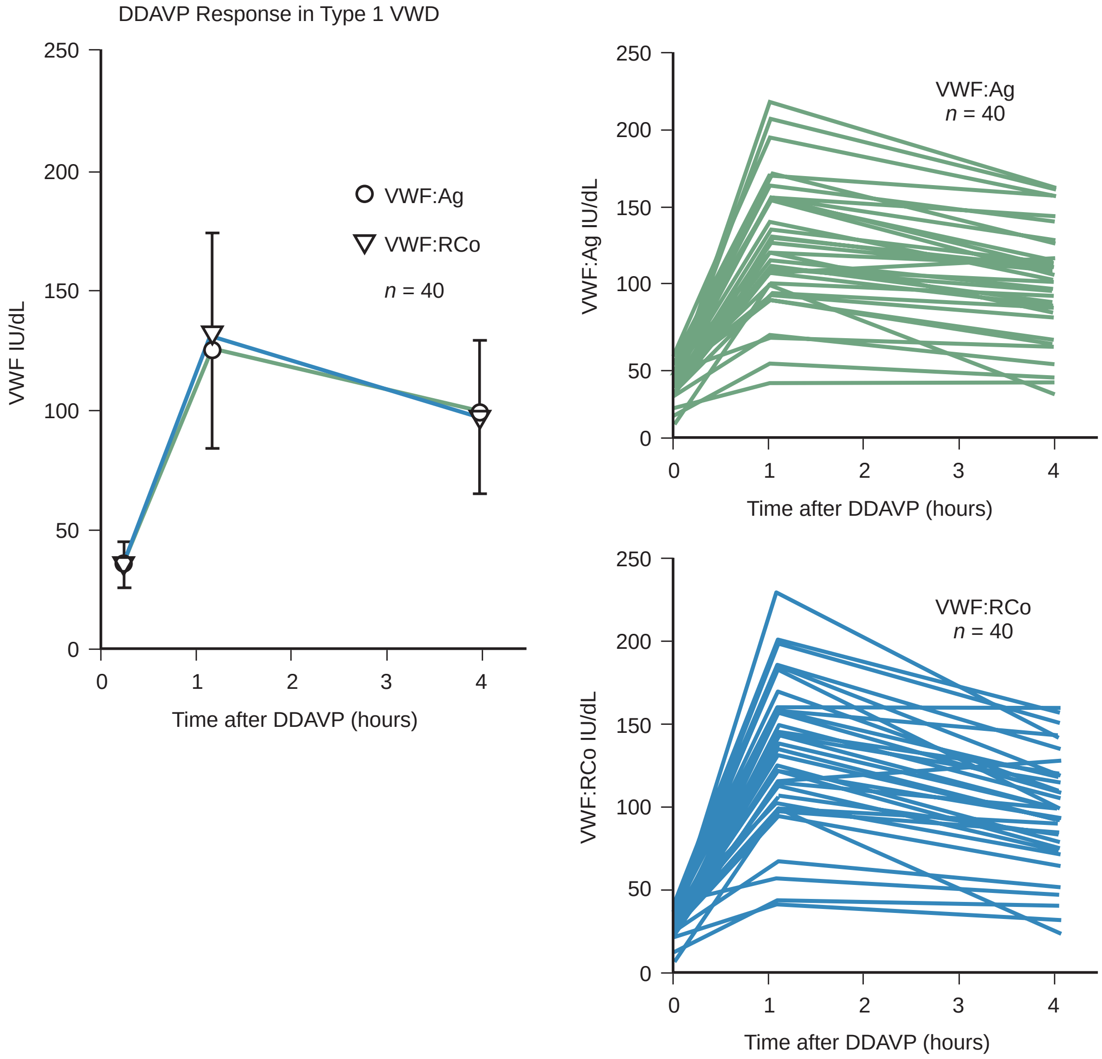

Figure 31-9 A patient with severe type 3 von Willebrand disease was infused with a von Willebrand factor (VWF) concentrate containing minimal amounts of factor VIII (FVIII). Within 15 minutes after infusion, VWF antigen (VWF:Ag) and ristocetin cofactor (VWF:RCo) are markedly increased. At 24 hours the factor VIII level in the patient has increased to 71 U/dL because of the endogenous production of factor VIII. *NP,* Normal plasma.

Although thrombocytopenia is usually present, therapy should be focused on correcting the plasma VWF level. The dose is identical to that used for the treatment of severe type 1 or type 3 VWD. If profound thrombocytopenia is present, concomitant administration of platelets may be necessary. Administration of platelets alone without replacement of VWF is not usually effective. Sometimes, pseudothrombocytopenia may be present and cause the platelet count to appear reduced as a result of platelet clumping.[369,371,372]

Although *platelet-type pseudo-VWD* is caused by a defect in the platelet GPIb receptor[373,374] (see Chapter 30), it is considered in the differential diagnosis of type 2B VWD because of the loss of high-molecular-weight multimers and reduced levels of VWF. The results of plasma VWF assays are identical to those for patients with type 2B VWD, but these disorders must be distinguished because of the markedly different approaches to therapy (see Fig. 31-3). Platelet-type pseudo-VWD should be treated with platelets.[375] Although the plasma level of VWF is reduced and the distribution of multimers is abnormal, these findings are secondary to the abnormal GPIb receptor on platelets. Thus as platelets are appropriately used to treat bleeding, the secondary VWF abnormalities will actually lessen. Standard doses of platelets are used to treat hemorrhage. If the hemorrhage is severe or if bleeding persists, VWF/factor VIII concentrates may be needed to correct the secondary deficiency of VWF. Similar to the normal platelet counts found in patients with intrinsic platelet disorders, the increment in platelets is not necessarily a good measure of the response to therapy because a nearly normal number of abnormal platelets will remain in the circulation. Improvement in the hemostatic abnormality may not become evident until a large proportion of the platelets are replaced by normal platelets from transfusion.

For patients with type 2N VWD, administration of desmopressin or recombinant factor VIII might have only a transient effect on factor VIII levels.[336] For a major bleeding episode or in preparation for surgery, the

preferred treatment is plasma-derived VWF/factor VIII concentrate.

Acquired von Willebrand Disease

Acquired VWD, also known as acquired von Willebrand syndrome, may be caused by at least three pathophysiologic mechanisms: (1) an acquired clinical state such as hypothyroidism resulting in decreased VWF synthesis, (2) an acquired autoimmune state in which an autoantibody develops against VWF and results in accelerated clearance of VWF (and usually factor VIII), or (3) a clinical disease develops in which VWF structure and function may be altered (Fig. 31-11).

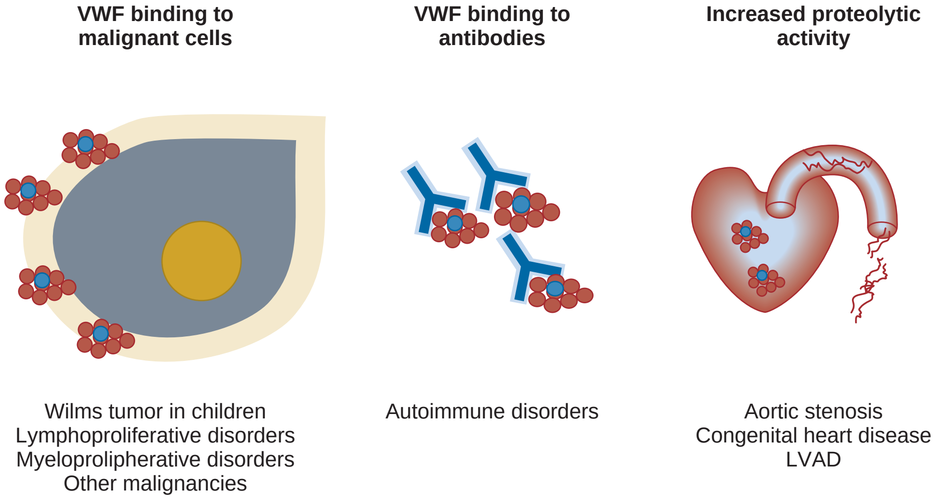
Congenital or acquired hypothyroidism can result in reduced VWF and subsequent bleeding symptoms.[318,376-379] Treating these patients to make them euthyroid results in normalization of the VWF level. If acute bleeding is present, the patient can generally be managed as would a patient with type 1 VWD, by administration of desmopressin or VWF concentrate. In hypothyroid patients the VWFpp level is usually reduced in parallel with the VWF level and suggests normal clearance of VWF.

Acquired VWD can also be the result of an isolated acquired autoantibody to VWF, autoantibody to VWF in autoimmune diseases (e.g., systemic lupus erythematosus), or monoclonal gammopathies.[380-382] Assays for an inhibitor of VWF:RCo activity are generally negative because the autoantibody is directed against other regions of VWF and promotes only clearance. An abnormal VWFpp/VWF:Ag ratio can be used to demonstrate increased clearance of VWF.[235,299,383] In monoclonal gammopathies, VWF multimers may demonstrate loss of high-molecular-weight multimers. Either plasmapheresis or a trial of intravenous immunoglobulin, or both, may sometimes be beneficial.[384,385] Desmopressin may also induce a transient rise in the VWF level, but its survival may be markedly reduced. Some success has been reported with recombinant factor VIIa.[386-388]

Wilms tumor has been reported to cause acquired VWD. In at least one case, synthesis of VWF was still present in endothelial cells in the removed kidney, and in another study the elevated hyaluronidase resulted in a reduced amount of VWF by Laurell quantitative immunoelectrophoresis.[389-392] Acquired loss of high-molecular-weight multimers has been identified in children with ventricular septal defects[294] and pulmonary hypertension[393,394] as well as in patients with aortic stenosis.[395]

von Willebrand Disease Without Known Subtyping

Occasionally, a clinician is called on to treat VWD when the appropriate subtype is not known and the patient's acute condition does not permit taking the time to collect appropriate samples to determine the subtype. In such instances a blood sample should be obtained for appropriate subtyping of VWD, followed by a carefully monitored therapeutic trial of desmopressin, VWF concentrates, or both. The response to such treatment should



VWF binding to malignant cells
VWF binding to antibodies
Increased proteolytic activity
Wilms tumor in children
Lymphoproliferative disorders
Myeloproliphertive disorders
Other malignancies
Autoimmune disorders
Aortic stenosis
Congenital heart disease
LVAD

Figure 31-11 Mechanisms that account for acquired von Willebrand disease and the conditions and diseases associated with it.

be monitored by close observation of the platelet count and the response of VWF activity and its survival. In a patient with known but untyped VWD and major hemorrhage, VWF/factor VIII concentrates are probably the preferred treatment. This therapeutic approach will appropriately treat all forms of VWD, with the exception of platelet-type, pseudo-VWD. The use of desmopressin may be either ineffective or exacerbate thrombocytopenia in patients with type 2A or type 2B VWD, respectively.

Thus therapy for VWD must be closely integrated with the correct laboratory diagnosis and often requires intensive laboratory monitoring through one episode of treatment. However, once an appropriate response is obtained with a given therapy, such monitoring can be greatly curtailed.

General Comments on the Treatment of von Willebrand Disease

Although the previous section presents the current clinical approach to VWD, many unanswered questions remain. Our current clinical approach may overdiagnose type 1 VWD because of the presence of low plasma VWF levels (see the earlier section on low VWF versus type 1 VWD). Because these patients in general have a preexisting history of excessive bleeding, we do not always know the contribution of their low VWF levels to these symptoms. We therefore generally treat them as having VWD. However, in postsurgical states in normal individuals, it is not uncommon to have VWF and factor VIII levels in excess of 200 to 300 IU/dL, yet we usually focus our therapy only to achieve a hemostatic level above 60 to 100 IU/dL. Whether the normal postsurgical elevation is a pathologic state brought on by surgical stress or a physiologic response to adapt to the surgical stress remains unknown. Normally, VWF is present in plasma, endothelial cells, platelets, and subendothelial matrix. When we treat a patient with type 3 VWD, we normalize only plasma VWF; endothelial cells, platelets, and subendothelium remain abnormal, and their relative contribution to hemostasis is not fully defined. If clinical bleeding continues in the absence of adequate plasma VWF and factor VIII, consideration should be given to platelet transfusion as a means of providing normal platelet VWF.[396]

CHAPTER 32

Rare Hereditary Coagulation Factor Abnormalities

Kenneth A. Bauer and **Anish V. Sharda**

CHAPTER OUTLINE

FIBRINOGEN DISORDERS
Hypofibrinogenemia and Afibrinogenemia
Dysfibrinogenemia
PROTHROMBIN DISORDERS
Factor V Deficiency
Combined Deficiency of Factor V and Factor VIII
Factor X Deficiency
Factor VII Deficiency
Factor XI Deficiency
Factor XIII Deficiency
Contact Factor Deficiencies
ANTIPLASMIN DEFICIENCY
Plasminogen Activator Inhibitor 1 Deficiency
Antitrypsin Pittsburgh
MULTIPLE FACTOR DEFICIENCIES

Rare bleeding disorders consist of inherited quantitative or functional deficiencies of factors I (fibrinogen), II, V, VII, X, XI, and XIII; combined factor deficiencies, particularly of factors V and VIII; inherited quantitative or functional deficiencies of vitamin K–dependent factors; and disorders of excessive fibrinolysis. Rare bleeding disorders constitute about 3% to 5% of all inherited bleeding disorders.[1] Many of these disorders, which are variable in their bleeding phenotype, may be encountered in the neonatal period and early childhood, whereas others present later in life. Each of these disorders is reviewed in this chapter; however, the reader is referred to reviews or hemostasis texts in the references for a more complete description of these abnormalities.

FIBRINOGEN DISORDERS

Fibrinogen is the most abundant clotting factor in human plasma, with normal concentrations ranging between 200 to 450 mg/dL. The hereditary fibrinogen deficiency states (afibrinogenemia and hypofibrinogenemia) and functional abnormalities (dysfibrinogenemias), which account for only 7% of the rare bleeding disorders in the most recent World Federation of Hemophilia annual survey, are among the rarest of the rare bleeding disorders.[1] These disorders should be considered when a prolonged thrombin time (TT) is found in a patient with a history of bleeding who is otherwise essentially healthy. Prolongations of the prothrombin time (PT) and activated partial thromboplastin time (APTT) are found in patients with afibrinogenemia and variably in patients with severe hypofibrinogenemia and some types of dysfibrinogenemia, with PT being more sensitive to a moderate decrement in plasma fibrinogen levels.

Hypofibrinogenemia and Afibrinogenemia

Genetic abnormalities that cause decreased fibrinogen synthesis may occur either as a heterozygous deficiency (hypofibrinogenemia) or as a homozygous deficiency (afibrinogenemia).[2] Clinical findings include ecchymoses, subcutaneous hematomas, hemarthroses, mucosal bleeding, menorrhagia, and postoperative bleeding. Because bleeding severity is strongly associated with fibrinogen activity, patients with fibrinogen activity levels of greater than 100 mg/dL seem to be completely protected from bleeding symptoms, whereas patients with activity levels greater than 70 mg/dL are protected from spontaneous bleeding.[3] Afibrinogenemia presents early in life, frequently in the neonatal period, with gastrointestinal bleeding, hemorrhage from delivery-associated trauma, and bleeding with circumcision. In contrast, patients with hypofibrinogenemia may remain undiagnosed until later in life; their condition may be detected as a result of preoperative screening or after posttraumatic bleeding, except in females, for whom menorrhagia may be the only symptom. Pregnancy complications, particularly spontaneous abortions and placental abruption, have also been reported and are known to occur in laboratory animals that have severe hypofibrinogenemia.[4,5] Surprisingly, symptoms in patients with afibrinogenemia are not as severe as those seen in persons with the classic hemophilic disorders.

Laboratory evaluation of a patient with afibrinogenemia reveals prolongations of the TT, PT, and APTT (see Chapter 29). The best screening tests to detect fibrinogen deficiency are the TT and reptilase time, which measure the time required for conversion of fibrinogen in plasma to a fibrin clot.[6] Reptilase is a thrombinlike enzyme obtained from snake venom. Unlike the TT, the reptilase time is unaffected by heparin treatment. Thus if one encounters a very prolonged TT, the possibility of heparinization must be considered, but marked prolongation of the reptilase time is suggestive of fibrinogen deficiency. Fibrinogen may be detected by functional, precipitation, or immunologic assays. The amount of fibrin clot needed for clot detection is greater with automated clotting instruments than with manual methods. Consequently, these tests are frequently prolonged to the limits of the instrument even though some fibrinogen may be present and a clot may be detected with use of manual methods. However, patients with afibrinogenemia generally have undetectable levels of fibrinogen. Although more than 80 distinct mutations in genes encoding fibrinogen have been identified, genetic testing of patients with afibrinogenemia and hypofibrinogenemia is of no direct value in guiding clinical management.[7]

Because fibrinogen is the ligand for the glycoprotein IIb/IIIa receptor that enables platelet aggregation, both the bleeding time and the results of platelet aggregation tests are usually abnormal. Interestingly, in the absence of fibrinogen, von Willebrand factor is able to bind to the glycoprotein IIb/IIIa complex on platelets and provides a backup mechanism for platelet aggregation,[8,9] which may result in a reduction in symptoms associated with this disorder. In many patients a small amount of platelet fibrinogen might facilitate some of these interactions, although this fibrinogen is not believed to be derived from synthesis by megakaryocytes; rather, it is believed to be acquired from plasma.

Clinical bleeding episodes in patients with afibrinogenemia, similar to those observed in patients with hemophilia, require episodic replacement therapy. Because of the long plasma half-life of fibrinogen (about 4 days), prophylactic infusions of fibrinogen should be considered in patients with severe symptoms. With the availability of fibrinogen concentrates, fibrinogen replacement therapy has become simpler compared with cryoprecipitate and fresh-frozen plasma (FFP). RiaSTAP is the only fibrinogen concentrate available in the United States.[10] Because it is derived from pooled human plasma, the risk of transmission of bloodborne pathogens is always a possibility, although such transmission is exceedingly rare. Compared with cryoprecipitate, which has a fibrinogen content of about 10 mg/mL, the fibrinogen content of RiaSTAP is more than 20 mg/mL. Hemorrhagic symptoms are usually controlled by initially achieving plasma levels of 80 to 100 mg/dL and achieving maintenance at a level greater than 50 to 60 mg/dL until the bleeding subsides. To raise the fibrinogen level to 100 mg/dL in an afibrinogenemic patient, approximately 0.17 unit/kg of cryoprecipitate and 60 mg/kg of RiaSTAP must be infused.[11] Because of the prolonged half-life of fibrinogen, replacement therapy can be provided at intervals of 3 to 4 days.

Dysfibrinogenemia

Numerous dysfibrinogenemias, which are named after the city in which they were originally identified, have been reported.[7] Most dysfibrinogenemias are associated either with no clinical symptoms or with hemorrhage, whereas others, interestingly, are associated with a predisposition to venous or arterial thrombosis (see Chapter 33).[12] In one series more than half of patients experienced no clinical complications, whereas bleeding occurred in 25% and thrombosis occurred in 20%.[13] Functional abnormalities of fibrinogen are generally inherited in an autosomal-dominant manner. Occasionally, however, index cases are associated with consanguinity and major hemorrhagic or thrombotic symptoms. Hereditary dysfibrinogenemia that is associated with hemorrhage usually results in a prolonged TT. Laboratory evaluation for dysfibrinogenemia includes functional and immunologic assays for fibrinogen, which should show a normal level of fibrinogen antigen in the presence of reduced functional fibrinogen. The ratio of functional to antigenic fibrinogen is usually less than 0.5. The reptilase time may also be prolonged. An occasional person with dysfibrinogenemia may have a prolonged PT or APTT. The inability of some abnormal fibrinogen to clot completely in vitro can result in false-positive results in fibrin(ogen) degradation product tests. TT and reptilase time are often prolonged in persons who have dysfibrinogenemia associated with thrombosis, though the TT is substantially shortened in some variants.[14] Molecular testing may be of clinical significance in persons with dysfibrinogenemia because some mutations may be predictive of a bleeding phenotype and other mutations may be predictive of thrombosis, but currently molecular testing is only available through research laboratories.[15] Infusion of fibrinogen in the form of cryoprecipitate may be indicated in patients who have clinical bleeding, with a normal rate of survival of this fibrinogen to be expected. Fibrinogen concentrates are not approved for use in persons with dysfibrinogenemia but may be used off-label in patients with a severe bleeding diathesis.

Severe liver disease is occasionally associated with acquired dysfunction of fibrinogen.[16] Studies usually demonstrate that this disease is not hereditary in nature, and the liver disease is generally overt.

PROTHROMBIN DISORDERS

Prothrombin, or factor II, is a vitamin K–dependent glycoprotein with a plasma concentration of approximately 100 μg/mL. The hemostatic level of prothrombin is around 20% to 40%.[17] Prothrombin deficiency is exceedingly rare, with a prevalence of about 1 in 1 to 2 million people, but in a few North American series it has been noted to disproportionately affect Latinos.[18] Similar to congenital abnormalities of fibrinogen, defects in prothrombin present either as quantitative (hypoprothrombinemia, or type 1 disorders) or functional deficiency (dysprothrombinemia, or type 2 disorders).[19] Aprothrombinemia is incompatible with life. Hypoprothrombinemia is inherited as autosomal-recessive defects in the prothrombin gene, leading to decreased production of protein. The mutations resulting in dysprothrombinemia either cause defective activation of the prothrombin molecule by factor Xa or result in its altered interaction with fibrinogen. Occasionally prothrombin deficiency can occur in association with combined deficiency of other vitamin K–dependent factors because of mutations in either the γ-glutamyl carboxylase gene or the vitamin K epoxide reductase gene.[20]

Clinical presentation is strongly associated with the level of functional protein. Heterozygotes are usually asymptomatic, although postoperative bleeding has been reported. Clinical bleeding in homozygotes ranges from easy bruising and mucosal bleeding to severe posttraumatic or postoperative bleeding. Hematomas, umbilical cord bleeding, intracranial bleeding, and major hematomas after vaccination have been reported in the neonatal period.[18] Although the APTT may be slightly prolonged, the hallmark of disorders of prothrombin is usually a prolonged PT and a normal TT. In some cases of dysprothrombinemia, such as prothrombin Cardeza, the PT may be nearly normal even though prothrombin activity is markedly reduced,[21] and thus specific prothrombin assays comparing immunologic levels with functional levels are required to diagnose dysprothrombinemias. The lack of deficiencies of other vitamin K–dependent factors (i.e., factors VII, IX, and X) and liver-dependent factors (i.e., factor V and fibrinogen) usually directs attention to the diagnosis of a hereditary deficiency of prothrombin. Immunoassays and assays of electrophoretic mobility help identify dysprothrombinemia. Molecular testing is only available in the research setting and does not provide much clinical utility.

Treatments currently available for prothrombin deficiency include FFP and prothrombin complex concentrates (PCCs).[10,22] Acute bleeding episodes can be easily treated with FFP. A dose of 15 to 20 mL/kg will usually raise the factor level by about 25%. Given the long half-life of prothrombin (approximately 60 hours), transfusion volume is usually not an issue. Three-factor PCCs contain factors IX, X, and prothrombin and a small amount of factor VII; the amounts vary from product to product and from lot to lot. Four-factor prothrombin factor concentrates contain all four vitamin K–dependent procoagulant factors and the antithrombotic proteins C and S; a description of the actual units of each factor in each vial accompany the product. Four-factor PCCs are indicated for the urgent reversal of acquired coagulation factor deficiency induced by vitamin K antagonist (e.g., warfarin) therapy. These products are labeled and dosed on the basis of factor IX units. These products are not approved for prothrombin deficiency, but a dose of 20 to 30 units/kg will usually be hemostatic. Thrombotic complications resulting from supratherapeutic levels of other factors remain a potential problem. Antifibrinolytic agents are a useful adjunct to factor replacement but are best avoided in combination with PCCs.

Factor V Deficiency

Factor V deficiency, which was first reported by Owren in 1947, has also been termed *parahemophilia*.[23] Its prevalence has been estimated to be 1 in 1 million people with no ethnic predisposition.[1] It is transmitted autosomally and is generally symptomatic only in the homozygous or compound heterozygous state.[24] Factor V activity has limited correlation with bleeding severity. Mucocutaneous bleeding and hematomas are the most common symptoms, but hemarthroses, gastrointestinal tract bleeding, and central nervous system bleeding are rarely encountered. Menarche is frequently associated with severe menorrhagia. Both the PT and the APTT are prolonged, which usually prompts specific factor assays. Immunoassays for factor V are not readily available, and thus most cases are defined by identification of functional deficiencies of factor V with the use of clotting assays. Liver disease, disseminated intravascular coagulopathy, a factor V inhibitor, and combined factor V and VIII deficiency states must be ruled out before diagnosing factor V deficiency.

Clinical bleeding can be controlled with FFP, which is the only currently available source of factor V. Normal hemostasis is achieved with levels greater than 20%. In a patient with severe factor V deficiency, hemostasis can be achieved with a loading dose of 15 to 20 mL of plasma per kilogram of body weight. The half-life of factor V is 12 to 36 hours, and hence daily infusions of plasma are sufficient. Factor V is more labile in FFP compared with other hemostatic factors, and thus it is important to use FFP that is less than 1 to 2 months old. Mild mucocutaneous bleeding can be treated with antifibrinolytic agents.[25] In rare instances, alloantibodies to factor V can develop in patients with congenital factor V deficiency who are, of course, quite symptomatic, but their condition can generally be managed by infusing fresh platelets that contain normal platelet factor V and account for about 20% of circulating factor V.

Occasionally one may encounter a patient who has an acquired inhibitor to factor V. These patients have usually undergone surgical procedures in which topical bovine thrombin has been used.[26] A mixing study can be performed to confirm the presence of an inhibitor. Even though the PT is markedly prolonged, some of these patients do not have major hemorrhagic symptoms.

Combined Deficiency of Factor V and Factor VIII

More than 50 pedigrees featuring an autosomal-recessive bleeding disorder characterized by a combined deficiency of both factor V and factor VIII have been reported.[27,28] In some cases the mutations responsible for this disorder are in the “lectin mannose-binding 1” *(LMAN1)* gene (also known as endoplasmic reticulum–Golgi intermediate compartment protein, or ERGIC-53), which functions as a molecular chaperone from the endoplasmic reticulum to the Golgi apparatus in the biosynthesis of both factor V and factor VIII.[29,30] In other kindreds, this disorder is associated with mutations in the multiple coagulation factor deficiency 2 *(MCFD2)* gene.[31] *MCFD2* encodes a protein that forms a calcium-dependent stoichiometric complex with LMAN1 and acts as a cofactor in the intracellular trafficking of factors V and VIII. The disease is associated with a moderate bleeding tendency and plasma factor V and factor VIII levels of 5% to 30% of normal. Combined factor V and factor VIII deficiency is usually accompanied by fewer symptoms compared with hemophilia A, but when hemostasis is required, it generally can be achieved with FFP.

Factor X Deficiency

Factor X deficiency is a rare autosomal disorder estimated to have a worldwide incidence of about 1 in 1 million people; it is more prevalent in populations that practice consanguineous marriage, such as in Iran.[32,33] Factor X is a vitamin K–dependent factor produced by the liver, and activation of factor X by the "tenase" complexes is considered the first step in the common pathway of coagulation. Similar to other coagulation factors, deficiencies of factor X can also be classified as type 1, in which both antigenic and functional activity are proportionally decreased, and type 2, characterized by near-normal antigenic levels but reduced functional activity.[34] A reduced factor X level is identified by a factor X clotting assay. In patients with dysfunctional factor X, the factor X clotting assay is prolonged, but results of the immunoassay are normal.[35,36] Mucocutaneous bleeding together with posttraumatic bleeding are the most frequent bleeding symptoms. Hemarthrosis and intracranial bleeding are reported in persons with functional levels of less than 1%.[37] The diagnosis is usually suspected when both PT and APTT are prolonged. A factor X functional assay and immunologic assays to measure factor X antigen confirm the diagnosis. Additional assays include the Russell viper venom (RVV) time. RVV is a metalloproteinase that directly activates factor X, and the RVV time will be abnormal in persons with factor X deficiency, although this assay may be normal in persons with some type 2 factor X deficiencies. Factor X levels are low at birth and reach adult levels by about 6 months of age. Factor X levels may also be low in persons with liver disease, accompanied by low levels of factors II, V, VII, and IX.

The biologic half-life of factor X is about 40 hours. Factor X levels of 20 to 30 units/dL are generally associated with the cessation of hemorrhagic symptoms. Infusion of approximately 20 mL of FFP per kilogram of body weight followed by 6 mL/kg every 12 hours increases the level of factor X sufficiently to achieve hemostasis for minor bleeding episodes. Although not approved for the treatment of factor X deficiency, PCC can also be used to treat major hemorrhage (see the previous discussion regarding use of PCCs in persons with prothrombin deficiency); however, their use can potentially be thrombogenic. Although factor X is a vitamin K–dependent factor, vitamin K has no therapeutic effect on factor X in patients with a congenital deficiency. Antifibrinolytic agents can also be adjunctive but are best avoided in combination with PCCs.[34]

Although it is not usually a pediatric problem, amyloidosis may be associated with factor X deficiency because of adsorption of factor X to the amyloid material.[38,39] Therapeutic infusions are not generally efficacious in patients with acquired deficiency of factor X as a result of amyloidosis.

Factor VII Deficiency

Factor VII deficiency has an estimated incidence of 1 per 500,000 in the general population worldwide.[40] Inherited as an autosomal-recessive disorder, the hemorrhagic predisposition in affected patients is highly variable and correlates poorly with plasma factor VII activity levels.[41,42] Heterozygous deficiency is not usually associated with hemorrhagic symptoms. Patients with levels that are less than 1% of normal can experience severe bleeding episodes, including hemarthroses and crippling arthropathy, comparable with patients who have the classic hemophilias. Neonates who have factor VII deficiency are at increased risk for the development of intracranial hemorrhage, which is attributable to trauma at the time of delivery.[42]

Hemostasis screening tests in patients with factor VII deficiency reveal a prolonged PT with a normal PTT and a normal TT. Heterozygotes typically have normal PTs and are identified only after specific factor VII assays are performed in family members of patients who have homozygous or compound heterozygous factor VII deficiency. Laboratory evaluation of factor VII deficiency relies on specific assay of plasma factor VII coagulant activity with the use of animal or human thromboplastin, as well as immunologic quantitation of factor VII antigen.[43,44] Patients have been categorized by their plasma level of factor VII antigen or cross-reacting material (CRM; CRM–, low or absent antigen; CRM^R, reduced antigen; CRM+, normal antigen). CRM– defects result from defective factor VII biosynthesis or accelerated clearance in vivo, CRM+ defects are structurally abnormal factor VII molecules, and CRM^R defects may result from a combination of these mechanisms. Some CRM^R or CRM+ factor VII molecules give variable plasma factor VII coagulant activity results when assayed with tissue factor from different animal species (e.g., rabbit brain, ox brain, simian brain, or human brain).[45-47] As anticipated, the molecular basis of factor VII deficiency is heterogeneous, and several different types of mutations have been described in patients with factor VII deficiency.[48] Most mutations have been missense mutations, but nonsense mutations, small deletions, splice site abnormalities, and promoter mutations have also been identified.

Factor VII is a vitamin K–dependent factor, but vitamin K administration is of no therapeutic benefit in the treatment of hereditary deficiencies. Although commercial PCCs may contain some factor VII, the amount is highly variable among the different commercial preparations. The factor VII content also varies between different lots produced by a single manufacturer. Because the plasma half-life of factor VII is short (approximately 3 to 6 hours), plasma infusions may not achieve adequate levels for normal hemostasis. Factor VII concentrates have been available for patients with factor VII deficiency in clinical trials or on a compassionate-use basis.[49]

The use of activated recombinant factor VII, which has a half-life similar to that of factor VII, has also been shown to provide effective hemostasis in patients with factor VII deficiency[50] and has been approved for this indication in many countries, including the United States. Anecdotally, the therapeutic effect of factor VII infusions appears to be longer than the time during which measurable factor VII levels can be identified in plasma. In one patient treated with PCCs on a regular basis, mucocutaneous bleeding was controlled for 3 to 4 days after a single infusion, even though factor VII was not measurable after 24 hours. It was not clear whether this control of mucocutaneous bleeding resulted from surface binding of factor VII to endothelial cells or platelets, removal of it from plasma, or some nonspecific effect from the concentrate infusion.

Factor XI Deficiency

Factor XI deficiency is usually inherited as an autosomal-recessive disorder. The APTT is prolonged in factor XI deficiency, whereas the PT is normal. A specific assay for factor XI coagulant activity is necessary to make the diagnosis. Factor XI assays are best performed on fresh plasma because the apparent factor XI level may be increased after freezing plasma.[51]

Although factor XI deficiency is most frequently encountered in Jewish persons of Ashkenazi descent, it is occasionally found in other ethnic groups, and the mutations have been characterized.[52,53,54] In Israel, 1 to 3 per 1000 Ashkenazi Jews are homozygous or doubly heterozygous for this deficiency, which calculates to a gene frequency of 4.3%.[55] Sephardic Jews, on the other hand, are rarely affected by factor XI deficiency. Three different point mutations in the factor XI gene account for nearly all cases of factor XI deficiency in Ashkenazi Jews: (1) a splice site mutation at the last intron that disrupts normal messenger ribonucleic acid processing (type I), (2) a nonsense mutation in exon 5 resulting in a premature stop codon (type II), and (3) a missense mutation in exon 9 resulting in substitution of Leu for Phe at 238-amino acid.[56] Although the genotype correlates well with plasma factor XI levels, there is not good correlation with the hemorrhagic tendency.[57] In Ashkenazi Jewish patients who are homozygous or doubly heterozygous for factor XI deficiency, the APTT is often longer than it is in patients with either severe factor VIII or factor IX deficiency.

Although factor XI deficiency has been termed *hemophilia C*, the bleeding tendency is highly variable, and bleeding almost always occurs in association with surgery or trauma. Epistaxis, soft tissue hemorrhage, and bleeding after dental extractions may occur, but hemarthroses and concomitant arthropathy are not seen. Affected women may experience menorrhagia. Even though low factor XI levels are not always associated with bleeding, patients with a significant personal or familial history of bleeding should probably receive FFP before major surgery. In the absence of such a history, prophylaxis with FFP should probably be administered for ear, nose, and throat (e.g., tonsillectomy), neurosurgical, cardiac, or urologic procedures. Patients who have previously undergone major surgery without bleeding or who are having minor procedures that can be controlled easily by local pressure (e.g., dental extraction) may be monitored closely, with initiation of treatment only if hemorrhage occurs. Heterozygous patients with factor XI levels greater than 20% of normal also may occasionally experience bleeding.[58]

Plasma infusions of 1 unit/kg body weight can increase the circulating factor XI concentration by about 1.5 unit/dL. A loading dose of 15 to 20 mL of plasma per kilogram will result in plasma levels of 20 to 30 units/dL, a level that is usually sufficient to control moderate hemorrhage. Additional plasma infusions of 7.5 to 10 mL/kg can be administered at 12- to 24-hour intervals until hemostasis is achieved. The half-life of factor XI is in excess of 48 hours. In factor XI–deficient patients who are deemed to be at risk for bleeding, antifibrinolytic agents such as ε-aminocaproic acid or tranexamic acid can be used to prevent hemorrhage after minor surgical procedures (e.g., dental extractions). A plasma-derived factor XI concentrate is available for use in Israel but not in most other countries.[10] The development of inhibitors to factor XI has been reported in patients with severe factor XI deficiency who have received prior treatments with plasma.[59]

Factor XIII Deficiency

Factor XIII (fibrin-stabilizing factor) is responsible for clot stabilization and cross-linking of the fibrin polymer, protecting it from fibrinolysis,[60] and hence deficiency of factor XIII is characterized by delayed bleeding. In a typical patient who sustains trauma on one day, a bruise or hematoma will develop on the following day. Other symptoms of factor XIII deficiency include delayed umbilical cord hemorrhage, delayed separation of the umbilical stump in the neonatal period (beyond 3.5 to 4 weeks), intracranial hemorrhage with little or no trauma, poor wound healing, and recurrent spontaneous abortions in women.[61] Although factor XIII is a heterodimer of two enzymatic A subunits and two carrier B subunits, most known cases are due to mutations in the A subunit.[62] The deficiency states of factor XIII are also classified as type 1, or antigenic deficiency, and type 2, or dysfunctional protein, with the latter being exceedingly rare.

Laboratory evaluation reveals normal hemostasis screening test results, including bleeding time, APTT, PT, and TT. For a patient with normal screening test results but clinical symptoms of a bleeding disorder, one must perform a factor XIII assay to avoid a misdiagnosis. Screening tests such as clot solubility tests have poor sensitivity but may be the only option in a resource-poor setting.

Recently a heat-treated, lyophilized, plasma-derived factor XIII concentrate, Corifact, has become available.[63,64] Because factor XIII has a very long half-life of 5 to 7 days and a level of 2 to 3 units/dL is hemostatic, the recommended dose of Corifact is 40 international units/kg every 28 days. When needed, an infusion of 5 to 10 mL/kg of FFP is also effective. Cryoprecipitate may also be used. One bag of cryoprecipitate contains 75 units of factor XIII.

Rare cases of acquired factor XIII deficiency as a result of autoantibody against factor XIII-A has been reported.[65] This deficiency is usually associated with autoimmune conditions, and neutralizing antibodies can be detected with mixing studies. Treatment is usually immunosuppression.

Contact Factor Deficiencies

Although factor XI deficiency may be associated with bleeding symptoms, deficiency in any of the other contact factors (i.e., factor XII, prekallikrein, and high-molecular-weight kininogen) is not associated with bleeding symptoms,[66] and thus these factors do not appear to play a major physiologic role in normal hemostasis (see Chapter 27). Because these contact factors function at the initiation step of the intrinsic system, the APTT in severely deficient individuals (i.e., persons with contact factor activity less than 1% of normal) frequently demonstrates prolongations beyond those seen with hemophilia A and hemophilia B. As a result, one encounters the paradoxic situation in which an extremely prolonged PTT is not associated with a bleeding disorder.

Clinicians usually encounter contact factor deficiency when they are asked to evaluate a patient without bleeding symptoms who is found to have a markedly prolonged APTT on a preoperative screening test. It is frequently advisable to carry out these same screening tests for other family members once the specific contact factor deficiency is determined to identify affected family members who could have future surgery inappropriately delayed because of the need for such clotting studies.

Paradoxically, in a number of case reports, venous thromboembolism or myocardial infarction has been noted in factor XII–deficient patients,[67] including the initial patient described with the abnormality. This thrombophilic tendency has been attributed to reduced plasma fibrinolytic activity.[67] In a literature review of 121 patients with factor XII deficiency, an 8% incidence of thromboembolism was found, including several myocardial infarctions in relatively young individuals.[68] Interpretation of such data is difficult because unlike in asymptomatic patients with factor XII deficiency, these complications are likely to be reported in the literature. This situation led some groups to perform cross-sectional analyses of thromboembolic events in larger numbers of unselected families with factor XII deficiency. In Swiss families with factor XII deficiency, 2 of 18 homozygous or doubly heterozygous patients had experienced deep venous thrombosis, although each episode occurred at a time when other predisposing thrombotic risk factors were present.[69] Among heterozygotes with factor XII deficiency, only 1 in 45 had a possible history of venous thrombosis. These investigators concluded that heterozygous factor XII deficiency does not constitute a major thrombotic risk factor, although a severe deficiency may predispose some affected persons to venous thrombosis. Other groups have found a 10% to 20% incidence of thrombotic episodes in heterozygotes.[70,71] Thus it remains uncertain whether an increased thrombotic risk is associated with factor XII deficiency.

ANTIPLASMIN DEFICIENCY

Antiplasmin is a major regulatory protein that controls the activity of plasmin, the pivotal enzyme in the fibrinolytic system that cleaves fibrin. In familial α_2-antiplasmin deficiency, the plasmin activity generated under physiologic conditions is poorly regulated and results in a bleeding disorder.[72] These patients have mucocutaneous bleeding and joint hemorrhage and must be differentiated from persons with mild hemophilia. The usual hemostatic screening test results are normal, including the PT, APTT, and TT. The euglobulin clot lysis time, a measure of fibrinolytic activity, is generally shortened. Although FFP contains α_2-antiplasmin, this clinical disorder is most commonly treated with the intermittent administration of antifibrinolytic agents, including ε-aminocaproic acid and tranexamic acid.

Plasminogen Activator Inhibitor 1 Deficiency

Deficiency of plasminogen activator inhibitor 1 (PAI-1) has been shown to cause a hereditary bleeding disorder.[73,74] In one homozygous case, the genetic defect was shown to be a frameshift mutation.[75] Affected patients can experience recurrent bleeding, especially after surgery or trauma. The PT, APTT, and TT are normal in such patients. The euglobulin clot lysis time can be abnormally short. Specific assays for PAI-1 antigen and activity are required to make a diagnosis of PAI-1 deficiency. Treatment with antifibrinolytic agents, such as tranexamic acid and ε-aminocaproic acid, is effective in treating bleeding complications.

Antitrypsin Pittsburgh

Antitrypsin is not normally a significant regulatory protein of hemostasis. However, several families with an alteration in the α_1-antitrypsin molecule (Met358Arg) have been described, conferring spontaneous antithrombin activity.[76] Continuous inactivation of thrombin results in delayed clot formation and a hemorrhagic syndrome that, like α_2-antiplasmin deficiency, resembles mild hemophilia. Therapy for a disorder featuring excessive antithrombin activity is more difficult than simple replacement in a patient with deficiency of a plasma protein.

MULTIPLE FACTOR DEFICIENCIES

Hereditary deficiencies of multiple factors are rare clinical disorders that are associated with a bleeding diathesis of variable severity. Combined deficiency of the vitamin K–dependent factors (i.e., factors II, VII, IX, and X) can result from deficient vitamin K–dependent γ-carboxylase activity,[77] which mediates posttranslational modifications of these proteins, or defective vitamin K metabolism as a result of mutations in vitamin K 2,3-epoxide reductase.[20,78] Vitamin K 2,3-epoxide reductase is the target of the oral anticoagulant warfarin. As mentioned earlier, factor V and factor VIII deficiency has been reported in more than 50 families. In general, when a patient with multiple factor deficiencies is identified, it is imperative to rule out acquired causes such as liver disease or vitamin K deficiency and to perform a family study before one assumes that such a defect is hereditary.

CHAPTER 33

Inherited Disorders of Thrombosis and Fibrinolysis

Cameron C. Trenor, III and **Kenneth A. Bauer**

CHAPTER OUTLINE

HEREDITARY THROMBOTIC DISORDERS
- Antithrombin III Deficiency
- Protein C Deficiency
- Protein S Deficiency
- Resistance to Activated Protein C and the Factor V Leiden Mutation
- Prothrombin G20210A Mutation

HYPERHOMOCYSTEINEMIA

DYSFIBRINOGENEMIAS

INHERITED ABNORMALITIES OF DIMINISHED FIBRINOLYSIS

MANAGEMENT OF PATIENTS WITH INHERITED THROMBOTIC DISORDERS
- Acute Thrombosis and Long-Term Management
- Antithrombin III Deficiency
- Coumarin-Induced Skin Necrosis
- Homozygous or Doubly Heterozygous Protein C Deficiency and Neonatal Purpura Fulminans
- Evaluation of Relatives of Patients with Hereditary Thrombophilia

For many years, researchers suspected that hereditary coagulation defects underlie a large percentage of venous thromboembolic events that could not be attributed to identifiable acquired risk factors. Acquired risk factors for venous thrombosis consist of a heterogeneous group of conditions and clinical disorders with diverse and poorly understood prothrombotic mechanisms. With expanding scientific knowledge of the hemostatic mechanism and the regulatory role of natural anticoagulants, major advances have been made in identifying hereditary defects in the heparan sulfate–antithrombin and protein C pathways during the past three decades. To date, whole genome screening and sequencing efforts have identified several additional genes of interest, although each individually makes a relatively small contribution to thrombotic risk.[1] In this chapter we review the hereditary disorders of thrombosis and fibrinolysis associated with an increased risk for thrombosis. Issues relating to diagnosis and treatment of the hereditary thrombophilias are also discussed.

HEREDITARY THROMBOTIC DISORDERS

Before 1980, the medical literature included only isolated reports of thrombosis in the pediatric population. Although, when compared with adults, thromboembolic events are uncommon in young patients, the incidence is increasing rapidly.[2] This increase is particularly true of children who experience stays in the hospital and is attributed to advances in critical care medicine, improved survival of high-risk patients (e.g., neonates and children with severe congenital heart disease), and increased awareness. The paucity of thrombotic events in children may be related more to vascular/endothelial factors than to hematologic factors, although some of the physiologic inhibitors do not attain full normal adult levels until mid childhood (e.g., protein C and protein S; see Chapter 5). Even patients with hereditary deficiencies of antithrombin (AT), protein C, or protein S, in association with moderate reductions in the levels of these natural physiologic anticoagulants, have few thrombotic symptoms during early childhood. During the past 30 years, however, more vigorous supportive and specific treatment measures for sick preterm infants have resulted in a markedly improved survival rate of even very preterm infants. Because these infants are quite prone to thrombotic events, the physiologic "hypercoagulability" of the developing hemostatic system has received increased attention and is discussed elsewhere (see Chapter 5). Thus the newborn infant can be expected to be at greater risk for thrombosis if he or she also has an underlying hereditary deficiency of an anticoagulant protein. Inherited alterations of coagulation proteins that have been clearly associated with a prethrombotic state are listed in Box 33-1.

Box 33-1 Inherited Alterations of Coagulation Proteins That Have Been Clearly Associated with a Prethrombotic State

- Antithrombin deficiency
- Protein C deficiency
- Protein S deficiency
- Resistance to activated protein C because of the factor V Leiden mutation (factor V Arg506Gln)
- Prothrombin G20210A mutation
- Dysfibrinogenemias (rare)

Antithrombin Deficiency

AT is a plasma protein synthesized by the liver that binds and neutralizes the serine proteases generated by the coagulation cascade, including thrombin, factor Xa, and factor IXa (see Chapter 27). Inhibition of these coagulation serine enzymes by AT is relatively slow but is markedly enhanced by binding to heparin. AT has two major active functional sites: the reactive center toward the carboxyl end and the heparin-binding site located at the amino terminus of the molecule. Thrombin cleaves the reactive site followed by the formation of an inactive complex, which is rapidly cleared from the circulation.

AT deficiency was the first hereditary hypercoagulable disorder identified. In 1965, Egeberg investigated a Norwegian family with a strong history of thrombosis and found that affected persons had plasma AT concentrations that were 40% to 50% that of normal concentrations.[3] Subsequent studies described families with similar clinical and laboratory abnormalities.[4,5] Heterozygosity for AT deficiency can be found in approximately 4% of families with inherited thrombophilia and in 1% of consecutive patients with a first episode of deep venous thrombosis.[6]

The thrombotic risk associated with AT deficiency depends on the population selected. In older reviews of AT deficiency that included families with a high penetrance of thrombosis, more than 50% of affected patients experienced venous thrombotic episodes.[7,8] The initial clinical manifestations occur spontaneously in about 42% of subjects but are related to pregnancy, parturition, hormonal contraceptives, surgery, or trauma in 58% of patients.[7] In children, the odds ratio (OR) of thrombosis with AT deficiency is estimated to be 9.44 (95% confidence interval [CI], 3.34 to 26.66).[9] The most common sites of disease are the deep veins of the leg and the mesenteric veins. Recurrent thrombotic episodes occur in approximately 60% of affected persons, and clinical signs of pulmonary embolism are evident in 40% of affected persons.[7] The literature includes case reports of neonatal and childhood arterial ischemic stroke in association with AT deficiency, but a causal relationship remains to be proven. Although cases have been reported in which AT-deficient infants sustained cerebral venous thrombosis,[7-9] thrombotic episodes are relatively uncommon in affected children before puberty, after which the risk of thrombosis increases substantially with advancing age.[7] First-degree relatives of symptomatic persons with AT deficiency have an eightfold to tenfold increased risk for thrombosis compared with the risk in noncarriers.[10,11] In the Leiden Thrombophilia Study—a case-control study of 474 consecutive patients after an initial episode of deep venous thrombosis[12]—the prevalence of AT deficiency was just 1.1%, and the OR for thrombosis was 5.0.[13]

AT deficiency is inherited in an autosomal-dominant fashion and thus affects both sexes equally. Two major types of inherited AT deficiency have been delineated (Table 33-1). The type I deficiency state is a result of reduced synthesis of biologically normal protease inhibitor molecules.[14] In these cases the antigenic and functional activities of AT in blood are reduced in parallel. The molecular basis of this disorder is either deletion of a major segment of the AT gene or, more commonly, the occurrence of small deletions/insertions or single base substitutions. These mutations introduce a frameshift, a direct termination codon, a change in messenger ribonucleic acid (mRNA) processing, or unstable translation products. The AT mutation database includes more than 100 distinct mutations in patients with type I deficiency.[15]

The second type of AT deficiency is produced by a discrete molecular defect within the protease inhibitor (type II). Plasma levels of AT are greatly reduced as judged by functional activity, whereas AT antigen is essentially normal. The first family with type II AT deficiency was described in 1974.[16] As additional families with this type II AT deficiency have been reported, they have been further subcategorized on the basis of two different functional assays of AT activity. The first is the antithrombin-heparin cofactor assay, which measures the ability of heparin to bind to lysyl residues on the inhibitor and catalyze the neutralization of coagulation enzymes such as thrombin and factor Xa. The second test is the progressive AT activity assay, which quantitates the capacity of this inhibitor to neutralize the enzymatic activity of thrombin in the absence of heparin.

Heterozygous type II patients with both diminished heparin cofactor activity and progressive AT activity have mutations near the thrombin-binding site at the carboxyl terminus of the molecule; patients with reductions only in heparin cofactor activity have mutations in the heparin-binding domain at the amino terminus of the molecule. The distinction between type II defects is clinically relevant because variants with heparin-binding site defects are infrequently associated with thrombotic events, except when they are present in the homozygous state.[17] Patients with homozygous mutations in the heparin binding site leading to AT deficiency were young children in whom severe venous or arterial thrombosis (or both) developed along with plasma antithrombin-heparin cofactor levels measuring less than 10%.[18,19] In each

TABLE 33-1 Assay Measurements in Heterozygous Antithrombin Deficiency

Type	Antigen	Activity	Heparin Cofactor	Progressive Antithrombin

II	Active-site defect	Normal	Low	Low
	Heparin-binding site defect	Normal	Low	Normal

instance, a history of parental consanguinity was noted, and the parents had type II AT deficiency with heparin-binding site defects.

The prevalence of type I AT deficiency in the adult population is approximately 1 in 2000.[20,21] Studies of healthy blood donors with functional assays that measure heparin cofactor activity have found a prevalence of AT deficiency in the general population of 1 in 250 to 1 in 500[22,23]; a substantial number, however, have a type II defect with mutations at the heparin-binding site.[21] The best single screening test for the disorder is the antithrombin-heparin cofactor assay, which measures inhibition of factor Xa; it is the functional AT assay that is most widely used today.

The mean concentration of AT in normal pooled plasma is approximately 140 µg/mL. Most laboratories report a normal range between 75% and 120% of normal pooled plasma for antithrombin-heparin cofactor determinations and a somewhat wider range for immunoassay results. A variety of pathophysiologic conditions can reduce the concentration of AT in blood. AT levels can drop substantially in patients with disseminated intravascular coagulation (DIC), sepsis, burns, and severe trauma but less commonly in the setting of acute thrombosis.[24] Reduced levels can also be seen in persons with liver disease as a result of decreased synthesis or in persons with nephrotic syndrome as a result of urinary protein loss.[25,26] Modest reductions are also found in users of oral contraceptives or estrogens.[27,28] In addition, the administration of heparin decreases plasma AT levels, presumably by accelerated clearance of the heparin-AT complex.[29] Thus evaluation of plasma samples from persons during a period of heparinization can potentially lead to an erroneous diagnosis of AT deficiency.

Healthy newborns have about half the normal adult concentration of AT[30,31] and gradually reach the adult level by 6 months of age.[32] Levels may be considerably lower in infants born at 30 to 36 weeks of gestation[32] and are even further reduced in infants with respiratory distress, necrotizing enterocolitis, sepsis, or DIC.[33] In the absence of heparin, AT contributes approximately 80% of the thrombin-neutralizing capacity of normal adult plasma.[34,35] The levels of a second thrombin inhibitor, α_2-macroglobulin, are higher during the first two decades of life than in adults, and this factor may lessen the risk for thromboembolic complications in AT-deficient patients during childhood.[36]

A number of clinical disorders can be associated with reductions in the plasma concentration of AT, and thus making a definitive diagnosis of the hereditary state is often difficult. Although an AT level in the normal range is usually sufficient to exclude the disorder, low levels should be confirmed at a later date. This determination is ideally performed when the person is no longer receiving warfarin because plasma AT concentrations can occasionally be elevated into the normal range in persons with the deficiency state. In such situations, clinical assessment of the person's risk for recurrent thrombosis will determine whether discontinuation of warfarin is feasible. In most AT-deficient subjects, however, this effect of oral anticoagulants is not of sufficient magnitude to obscure the diagnosis.[37] Confirmation of the hereditary nature of the disorder often leads to the investigation of other family members. Diagnosis of other affected family members allows appropriate counseling regarding the need for prophylaxis for venous thrombosis and avoidance of prothrombotic risk factors.

Protein C Deficiency

Protein C is a vitamin K–dependent protein synthesized by the liver that circulates as a zymogen. It exerts its anticoagulant function after cleavage to the serine protease activated protein C (APC). This activation process can be mediated by thrombin alone but occurs much more efficiently when thrombin is bound to thrombomodulin on endothelial cells (see Chapter 27).

In 1981, Griffin and colleagues[38] described low levels of protein C in a family with recurrent thrombotic events. Subsequently, reports were made of many other families with heterozygous protein C deficiency.[39-41] Heterozygous protein C deficiency is inherited in an autosomal-dominant fashion; a more severe form of protein C deficiency is an autosomal-recessive disorder. The phenotype of patients with heterozygous protein C deficiency is similar to that of persons with hereditary AT deficiency. In severely affected families, approximately 75% of protein C–deficient persons experienced one or more thrombotic events. The initial episode occurs spontaneously in approximately 70% of persons experiencing such events. The remaining 30% have the usual associated risk factors (e.g., pregnancy, parturition, hormonal contraceptives, surgery, or trauma) at the time that the acute thrombotic events take place. Symptoms occur infrequently until affected persons are in their early twenties, with increasing numbers of persons experiencing thrombotic events as they reach the age of 50 years.

The most common sites of disease are the deep veins of the legs, the iliofemoral veins, and the mesenteric veins. Approximately 63% of affected patients experience recurrent venous thrombosis, and approximately 40% exhibit signs of pulmonary embolism.[42] Superficial thrombophlebitis of the leg veins, as well as cerebral venous thrombosis, can occur in protein C–deficient patients.[39] The literature includes reports of nonhemorrhagic arterial stroke in children and young adults with hereditary protein C deficiency, but a causal relationship is unproven.

The prevalence of protein C deficiency in outpatients who have experienced an initial episode of venous thromboembolism (VTE) ranges from 0.5% to 4%.[6,13] In earlier reports of more select patient populations, protein C deficiency was more frequently identified and occurred in 2% to 9% of patients. Initial estimates placed the prevalence of protein C deficiency between 1 in 16,000 and 1 in 32,000 within the general population based on the assumptions that protein C was an autosomal-dominant disorder with high penetrance and that at least half the persons with the deficiency would demonstrate symptomatic thrombosis. However, it was difficult to reconcile this figure with the infrequent history of thrombosis in the parents of infants with purpura fulminans, which is due to the homozygous or doubly heterozygous form of protein C deficiency. This disparity led to studies of healthy blood donors in which a much higher prevalence of heterozygosity for protein C deficiency was found, ranging from 1 in 200 to 1 in 500.[43,44]

The risk of thrombosis initially attributed to protein C deficiency was subject to selection bias in that it was overestimated from familial reports. Data from the Leiden Thrombophilia Study indicate that heterozygous protein C deficiency is associated with about a sevenfold increased risk for an initial episode of deep venous thrombosis compared with persons who have normal protein C activity.[13] Among Italian patients, protein C deficiency is associated with a similar sevenfold increase in venous thrombotic risk.[10] In asymptomatic carriers of protein C deficiency, the incidence of thrombosis is fairly low, at 0.4% to 1.0% annually.[45] Similar to other inherited thrombophilias, this variability in phenotypic expression of protein C deficiency is not explained by differences in the particular genetic defect alone and probably represents a complex interaction with other modulating factors. In pediatric patients, the odds ratio of thrombosis with protein C deficiency is estimated at 7.72 (95% CI, 4.44 to 13.4).[9]

Two major subtypes of heterozygous protein C deficiency have been identified with the use of immunologic and functional assays (Table 33-2). The type I deficiency state is the most common form and is characterized by a similar degree of reduction in both the immunologic and biologic activity of protein C. More than 195 different mutations have been identified, most commonly missense or nonsense mutations.[46] The functional or type II deficiency state is characterized by normal synthesis of an abnormal protein. The functional capacity of protein C is most often assessed by using a snake venom protease (Protac)-based assay to directly activate the protein. After activation, an amidolytic assay can assess the functionality of the catalytic site of the protein. A few persons with normal levels of protein C antigen and amidolytic activity but with substantial reductions in protein C anticoagulant activity have been described.[47] In such cases, protein C anticoagulant activity can be measured with a clotting assay (based on prolongation of the activated partial thromboplastin time [APTT]), and abnormalities presumably reflect a reduced ability of activated protein C to interact with the platelet membrane or its substrates such as factor Va and factor VIIIa. The coagulant assay thus has the highest sensitivity in screening patients for hereditary protein C deficiency.

Levels of protein C antigen in the heterozygous deficiency state overlap with those in the normal population, thus making it difficult to define the diagnosis in some patients. In general, antigen levels of 60% to 70% of normal represent borderline values and warrant repeat testing. Protein C antigen levels can also vary with age. Protein C levels in newborns are 20% to 40% that of normal adult levels,[48] and preterm infants have even lower levels.[49] Neonates with significant perinatal thrombosis can have levels suggestive of homozygous deficiency (<10%).[50] Protein C levels often reach adult levels by 1 year of age (see Chapter 5), although further increases are reported into adolescence. In adults, protein C levels typically increase 4% per decade.[43]

TABLE 33-2 Assay Measurements in Heterozygous Protein C Deficiency

		Activity	
Type	**Antigen**	**Amidolytic**	**Coagulant**
I	Low	Low	Low
II	Normal Normal	Low Normal	Low Low

Acquired protein C deficiency is found in numerous disease states, including liver disease, DIC, sepsis, and acute thrombosis. A particularly severe form of acquired protein C deficiency has been reported in association with purpura fulminans and DIC in persons with acute meningococcal infections.[50,51] In contrast to AT, antigenic concentrations of vitamin K–dependent plasma proteins, including protein C, are often elevated in persons with nephrotic syndrome.[52] Most persons with uremia have low levels of protein C anticoagulant activity but normal levels of protein C amidolytic activity and antigen.[53] This situation is attributable to a dialyzable moiety in uremic plasma that interferes with most clotting assays for protein C activity.[54]

As for other γ-carboxylase coagulation proteins (see Chapter 27), warfarin therapy reduces functional and, to a lesser extent, immunologic measurements of protein C, thus complicating diagnosis of the deficiency state.[47] Several researchers have proposed that the diagnosis can still be made in this setting on the basis of the ratios of protein C antigen to factor II or factor X antigen. However, this method will not detect patients with type II deficiency, and it can be used only in subjects in a stable phase of oral anticoagulation.[55] Other groups have used protein C activity assays in conjunction with functional measurements of factor VII, a vitamin K–dependent zymogen with a similar plasma half-life.[56] In practice it is preferable to investigate persons suspected of having the deficiency state either before the initiation of oral vitamin K antagonists or after these medications have been discontinued for at least 1 week, and family studies should also be performed. In patients in whom discontinuation of warfarin is impossible because of the severity of the thrombotic diathesis, studies can be performed while they are undergoing therapy with heparin, which does not alter plasma protein C levels.

Warfarin-induced skin necrosis has been associated with the presence of heterozygous protein C deficiency.[57-59] This syndrome typically manifests during the first several days of warfarin therapy, often in association with the administration of large loading doses of the medication. Skin lesions occur on the extremities, breasts, trunk, and penis and marginate over a period of hours from an initial central erythematous macule. If a product that contains protein C is not administered rapidly, the affected cutaneous areas become edematous, central purpuric zones develop, and the lesions ultimately become necrotic. Biopsies demonstrate fibrin thrombi within cutaneous vessels with interstitial hemorrhage. The dermal manifestations of warfarin-induced skin necrosis are clinically and pathologically similar to those seen in infants who have purpura fulminans resulting from severe protein C deficiency (discussed later).

The pathogenesis of warfarin-induced skin necrosis is attributable to the emergence of a transient hypercoagulable state. Initiation of the drug at standard doses leads to a decrease in protein C anticoagulant activity to approximately 50% of normal within 1 day.[47] Although factor VII activity follows a pattern similar to that of protein C, levels of the other vitamin K–dependent factors decline at slower rates, consistent with their longer half-lives. Increased thrombin generation has been documented in patients during this early phase of warfarin therapy.[60] During this period the drug's suppressive effect on protein C has a greater influence on the hemostatic mechanism than does its reduction of factor VII. Only about a third of patients with warfarin-induced skin necrosis have an inherited deficiency of protein C,[61] and this complication is a rather infrequently reported event in persons with the heterozygous deficiency state. This syndrome has been reported in association with an acquired functional deficiency of protein C.[62] Reports also have been made of hereditary protein S deficiency and the factor V Leiden mutation in association with warfarin-induced skin necrosis.[63-66]

The long-established syndrome of purpura fulminans is classically described as a complication of meningococcal infection in children. However, newborns rarely exhibit a syndrome of purpura fulminans, which is associated with laboratory evidence of DIC and protein C antigen levels that are less than 1% of normal.[67-76] In some instances a history of consanguinity exists in the family, leading to homozygous deficiency of affected infants.[68,71,74] Affected newborns can also be double heterozygotes, as was demonstrated in a Chinese patient[72] who had a five-nucleotide deletion in one protein C allele and a missense mutation in the other.[77] The heterozygous parents of infants with purpura fulminans in association with severe protein C deficiency only infrequently have thromboses, in contrast to patients with thrombotic histories and a hereditary partial deficiency of protein C. However, numerous reports have been made of older patients with homozygous or doubly heterozygous protein C deficiency in whom purpura fulminans was not present. These persons generally had protein C levels that were less than 20% of normal in the absence of oral anticoagulant therapy, and their clinical manifestations were similar to those of severely affected subjects from thrombophilic kindreds with the heterozygous deficiency state.[78,79]

Protein S Deficiency

Protein S is a vitamin K–dependent protein that enhances the anticoagulant effect of APC. Primarily synthesized by hepatocytes but also by endothelial cells, megakaryocytes, and brain cells, protein S serves as a cofactor for APC, which then inactivates factors Va and VIIIa. Factor Va inactivation occurs by an ordered series of peptide bond scissions in the molecule's heavy chain: first, rapid cleavage at Arg506 takes place, followed by slower cleavage at Arg306 and then Arg679 (see Chapter 27).[80] Interaction of protein S with APC results in both an increased affinity for negatively charged phospholipids and a twentyfold enhancement of the slower phase of factor Va inactivation. In plasma, only 40% of protein S is available in the "free" form, whereas the remainder is bound to C4b-binding protein and cannot interact with APC.

Protein S deficiency is an autosomal-dominant disorder that was originally described in 1984 in several kindreds with low levels of protein S and a striking history of recurrent thrombosis.[81,82] A frequency of thrombosis of approximately 10% has been reported in families with inherited thrombophilia[10,83]; however, the prevalence is lower (between 1% and 7%) in consecutive outpatients with a first episode of deep venous thrombosis.[6,13] Protein S deficiency is generally considered to confer a risk of thrombosis similar to that in persons with protein C deficiency, although the association has been complicated by considerable phenotypic variability.

The clinical findings in patients with heterozygous protein S deficiency are similar to those outlined for deficiencies of AT and protein C. Among 71 protein S–deficient members from 12 Dutch pedigrees,[84] 74%, 72%, and 38% of the individuals sustained deep venous thrombosis, superficial thrombophlebitis, and pulmonary emboli, respectively. The mean age at the first thrombotic event was 28 years, with a range of 15 to 68; 56% of the episodes were apparently spontaneous, and the remainder were precipitated by an identifiable factor. Thrombosis has also been reported in the axillary, mesenteric, and cerebral veins. In pediatric patients with VTE, the OR for thrombosis attributed to protein S deficiency is estimated to be 5.77 (95% CI, 3.03 to 11.0).[9] Although the literature includes case reports of young patients with arterial thrombosis (including arterial ischemic stroke) who were found to have protein S deficiency, current data have not established causation between hereditary protein S deficiency and an increased risk for arterial thrombosis.[85]

Three types of protein S deficiency states can be identified on the basis of measurements of total and free antigen, as well as functional activity (Table 33-3). The type I deficiency state is associated with approximately 50% of the normal total protein S antigen level[82] and greater reductions in free protein S antigen and protein S functional activity.[86] This defect is most often a result of missense mutations and base pair insertions or deletions. The type II qualitative deficiency state, characterized by normal total and free protein S levels but abnormal functional activity, has been identified infrequently, thus

TABLE 33-3 Assay Measurements in Heterozygous Protein S Deficiency

Type	Protein S Antigen	PROTEIN S ACTIVITY	
		Total	Free
I	Low	Low	Low
II	Normal	Normal	Low
III	Normal	Low	Low

suggesting that current functional assays may not screen for all such defects. In persons with type III deficiency, total protein S antigen levels are normal, with disproportionately decreased free protein S and functional activity. Thus initial evaluation for protein S deficiency should test for protein S functional activity.

The biologic basis of the type III protein S deficiency state is uncertain. Furthermore, coexistence of type I and type III deficiency has been reported in some protein S–deficient families, which has led to the proposal that the two types of protein S deficiency are phenotypic variants of the same genotype and are not the product of distinct genetic mutations.[87] In a follow-up analysis of one large family that had a high prevalence of both type I and type III deficiency, total protein S antigen levels—but not free protein S antigen levels—were shown to directly correlate with age.[88] These findings were independent of gender and were also seen in nondeficient family members. The researchers concluded that a single point mutation in the protein S gene was responsible for the quantitative type I deficiency but that the type III phenotype was actually due to an age-dependent free protein S deficiency; with increasing age, the relative concentrations of free protein S to total protein S decreased. However, in a Dutch cohort study of first-degree family members with protein S deficiency it was found that affected relatives of probands with type I deficiency were at increased risk for VTE, whereas affected relatives of probands with type III deficiency were not at increased risk for VTE.[85]

Acquired protein S deficiency has multiple causes, including pregnancy and oral contraceptive use. Protein S levels are commonly low in inflammatory states, including DIC and acute thrombosis, largely because of protein S interaction with C4b-binding protein. C4b-binding protein is an acute phase reactant and shifts protein S to the complexed, inactive form, which leads to decreased protein S activity.[89] Levels of total and free protein S are significantly reduced in men infected with human immunodeficiency virus.[90] Although total protein S antigen measurements are generally increased in persons with nephrotic syndrome, functional assays are often reduced[52] because of loss of free protein S in urine and elevated C4b-binding protein levels.

The lower limit of normal total and free protein S in plasma is approximately 65%; however, considerable overlap exists between the heterozygous deficiency state and levels at the low end of the normal range. Such overlap is largely due to the influence of age, which leads to an increase in protein S levels, and the influence of gender, with females having a lower normal limit for plasma protein S levels compared with males. Thus it is difficult to diagnose heterozygous protein S deficiency by performing a single assay; repeat sampling and family studies are usually required to make the diagnosis.

An epidemiologic study demonstrated that adults with low protein S levels and a negative family history of venous thrombosis have minimal, if any, increase in risk of a first episode of VTE.[91] Among 5317 patients and control subjects evaluated, a free protein S level below the 2.5th percentile (i.e., <53 units/dL) did not confer an increased risk of thrombosis compared with a higher free protein S level (OR, 0.82; 95% CI, 0.56 to 1.21). A free protein S level below the 0.10th percentile (i.e., <33 units/dL) was associated with an increase in risk of VTE that was not statistically significant (OR, 5.4; 95% CI, 0.61 to 48.8). Total protein S levels did not correlate with thrombosis, even below the 0.10th percentile. The results of this study imply that the increased risk of VTE is minimal in persons with protein S deficiency in the absence of a family history.

Young patients with recurrent VTE disease associated with doubly heterozygous or homozygous protein S deficiency have been identified.[81] The parents of these patients were asymptomatic and had laboratory studies consistent with type I protein S deficiency. Neonatal purpura fulminans has been described in association with homozygous protein S deficiency.[92,93]

Resistance to Activated Protein C and the Factor V Leiden Mutation

Before 1993, hereditary deficiencies were infrequently identified in patients with familial thromboembolic disease. Dahlbäck and colleagues[94] identified several probands with venous thrombosis that appeared to be resistant to APC in an APTT-based clotting assay. When compared with control subjects, many family members of the probands also had a blunted anticoagulant response to APC. The following year, Bertina and colleagues[95] identified the genotype underlying most cases of APC resistance as a single point mutation in the factor V gene, leading to substitution of Arg506 by glutamine. This mutation at an APC cleavage site renders factor Va relatively resistant to inactivation by APC.[80,95]

After the description of APC resistance by Dahlbäck and colleagues,[94] several studies revealed that this defect was relatively common in persons with venous thrombosis. In 1994 Svensson and Dahlbäck[96] screened 104 consecutive Swedish persons referred for evaluation of venous thrombosis and found that 33% of the subjects demonstrated APC resistance. In a U.S. referral population of persons younger than 50 years who had unexplained VTE disease, Griffin and colleagues[97] found that approximately 50% exhibited APC resistance.

Dutch investigators had previously initiated the Leiden Thrombophilia Study to identify risk factors for a first episode of venous thrombosis. Excluding patients with known malignancies, 345 consecutive outpatients younger than 70 years who had confirmed deep venous thrombosis were initially reported.[98] With use of a screening APTT-based assay, APC resistance was identified in 21% of persons with thrombosis and in 5% of age- and sex-matched healthy control subjects. The factor V Arg506Gln (or factor V Leiden) mutation was found in more than 80% of the patients who had been found to be APC resistant.[95] The lower frequency of APC resistance identified in the Leiden Thrombophilia Study compared with previous studies is attributable to differences in selection criteria and referral cohorts.

The U.S. Physicians' Health Study has also provided valuable data regarding factor V Leiden as a risk factor for venous and arterial thrombosis. In a retrospective case-control study of 14,916 healthy men older than 40 years with a mean follow-up period of 8.6 years, heterozygosity for the factor V Leiden mutation was identified in 12% of patients (14/121) who had a first episode of deep venous thrombosis or pulmonary embolism and in 6% of control subjects.[99] The relative risk for VTE was increased 3.5-fold in persons with no other concomitant risk factors but was reduced to 1.7-fold in persons who had preexistent cancer or had recently undergone surgery. This study also showed that elderly patients with venous thrombosis frequently have the mutation.[99] Among men older than 60 years who had initial episodes of venous thrombosis and no identifiable triggering factors, 26% (8/31) were heterozygotes for factor V Leiden mutation.

A cohort study of more than 9000 randomly selected adults in Denmark found that the simultaneous presence of smoking, obesity (body mass index >30 kg/m^2), older age (>60 years), and the factor V Leiden mutation resulted in absolute 10-year VTE rates of 10% in heterozygotes and 51% in homozygotes.[100]

A systematic review and meta-analysis of pediatric studies found that factor V Leiden heterozygosity conferred an odds ratio of 3.77 (95% CI, 2.98 to 4.77) for a first episode of VTE and 0.64 (95% CI, 0.35 to 1.18) for recurrent VTE in children.[9] In a cohort of children who had spontaneous VTE, factor V Leiden still did not increase the risk of recurrent thrombosis (OR, 1.35; 95% CI, 0.91 to 1.98). A systematic review and meta-analysis of observational studies, including pediatric patients with cerebral sinovenous thrombosis, reported an OR for thrombosis of 2.74 (95% CI, 1.73 to 4.34) in factor V Leiden mutation carriers.[101]

A prospective cohort study determined the incidence of VTE in asymptomatic carriers of the factor V Leiden mutation who were identified through family studies of symptomatic probands. Nine events occurred in 1564 observation-years, for an annual incidence of 0.58%. It was concluded that the absolute annual incidence of VTE in asymptomatic carriers of the mutation is low.[102]

A number of studies have examined whether factor V Leiden mutation, a prevalent abnormality in white populations, leads to an increased risk for arterial thrombotic events. No convincing data are available to indicate that other thrombophilic states such as deficiencies of AT, protein C, and protein S confer an increased risk for arterial thrombosis, but evaluation of these associations is complicated by the relative infrequency of these defects. In a cohort of men older than 40 years who had a low prevalence of smoking in the U.S. Physicians' Health Study, an association was not found between the factor V Leiden mutation and myocardial infarction or stroke.[99] In a younger cohort of Italian patients who experienced myocardial infarction before 45 years of age, an increased incidence of the factor V Leiden mutation relative to that in control subjects also was not found.[103] Like other hereditary thrombophilic states, factor V Leiden has been associated with pediatric arterial ischemic stroke,[101] although data are lacking to prove causation.

Because of the frequency of heterozygosity for the factor V Leiden mutation in white persons, homozygosity is not a particularly rare occurrence, and its presence is compatible with normal gestational survival. However, homozygotes for factor V Leiden are at significantly higher risk for venous thrombosis than are heterozygotes[104,105] and demonstrate heightened APC resistance in APTT assays.[95,104,106] Patients with heterozygosity for the factor V Leiden mutation along with deficiencies of protein C, AT, or protein S[107-111] are also at significantly greater risk for VTE than are persons who have only a single genetic defect. The genes for factor V and AT are both located on the long arm of chromosome 1, thereby allowing coinheritance of the factor V Leiden mutation and an AT mutation within all affected members of a family. This situation is expected to lead to an even more severe thrombotic diathesis.[109]

Obstetric complications such as severe preeclampsia, abruptio placentae, fetal growth retardation, and stillbirth are associated with intervillous or spiral artery thrombosis and consequent placental insufficiency. Factor V Leiden, as well as other hereditary thrombophilias, is associated with an approximate tripling of the risk for late fetal loss.[112,113] In contrast, first-trimester loss does not correlate with factor V Leiden or other hereditary thrombophilias. An increased incidence of factor V Leiden, as well as other thrombophilias, was also reported in women in association with other obstetric complications[114]; however, associations with preeclampsia and intrauterine growth restriction/retardation have not been corroborated.[115,116]

The prevalence of heterozygosity for the factor V Leiden mutation in white persons, including European, Jewish, Israeli Arab, and Indian populations, ranges between 1% and 8.5%. The mutation apparently is rare (<1%) in African blacks and in Chinese, Japanese, or Native American populations.[117] In Europe, the mutation has been found to be more prevalent in northern countries such as Sweden than in southern countries such as Spain and Italy. By using dimorphic sites in the factor V gene to perform haplotype analysis, data have been provided that support the existence of a single founder allele among whites of differing ethnic backgrounds.[118] It was also estimated that the mutation originated approximately 30,000 years ago, after the evolutionary divergence of white, African, and Asian populations.

Two mutations at the Arg306 residue in factor V, the second APC cleavage site in the activated cofactor, have been described in patients who have a history of thrombosis. These mutations are replacement of Arg306 with threonine (factor V Cambridge)[119] and with glycine (in Chinese persons from Hong Kong).[120] The latter mutation, however, evidently has no clinical relevance because it is not associated with APC resistance and the mutation is as common in healthy Chinese blood donors as it is in patients with thrombosis (4.5% and 4.7%, respectively).[121] The factor V Cambridge mutation is extremely rare among white persons with VTE disease.

Co-segregation of heterozygous APC resistance as a result of the factor V Leiden mutation and type I factor V deficiency has been reported in some patients.[122-124] The plasma of these persons manifests severe APC resistance in partial thromboplastin time (PTT) assays, as found in homozygous factor V Leiden patients (i.e., the patients with such co-segregation are pseudohomozygous). These patients were seemingly more prone to thrombosis than were heterozygous relatives with factor V Leiden alone, thus suggesting that their clinical phenotype is similar to that of homozygous factor V Leiden patients.

Several polymorphisms are present in the factor V gene.[125,126] An extended factor V gene haplotype (HR2) containing the R2 polymorphism (His1299Arg) is associated with mild APC resistance and occurs with increased frequency in heterozygous patients with the factor V Leiden mutation and the lowest APC resistance ratios.[126] Although one case-control study found that the R2 allele was a risk factor for VTE with an OR of 2.0 after excluding subjects with genetic defects such as factor V Leiden,[127] another case-control study found no significant increase in risk.[128]

The initial observations of Dahlbäck and colleagues[94] facilitated the development of a PTT-based assay that serves as a screening test for APC resistance. The PTT assay is performed in the presence or absence of a standardized amount of APC, and the two clotting times are converted to an APC ratio. Results can be interpreted by comparing the ratio with the normal range or by normalizing it to the APC resistance ratio obtained with normal pooled plasma. Although this first-generation APC resistance assay was conceptually quite simple and easy to perform in a coagulation laboratory, it required careful standardization and determination of the normal range in at least 50 control subjects. The level of APC, the PTT reagent, and the instrumentation used for clot detection affected the performance characteristics of the assay. Some assays using this format therefore had inadequate sensitivity and specificity for the factor V Leiden mutation. Moreover, patients who were receiving anticoagulants or had an abnormal PTT because of other coagulation defects could not be evaluated with this assay, and the test was not validated in patients with acute thrombosis or in pregnant women.

The discovery that factor V Leiden is the dominant genetic defect responsible for APC resistance facilitated the development of second-generation coagulation tests that, with proper standardization, can provide nearly 100% sensitivity and 100% specificity for detection of the mutation. For these tests, patient plasma is diluted in a sufficient volume of factor V–deficient plasma, and a PTT-based assay is then performed. This modification also permits evaluation of the plasma of patients who are receiving anticoagulants or have abnormal PTT results because of coagulation factor deficiencies other than factor V.

Because the dominant mutation underlying APC resistance is factor V Leiden, diagnosing this defect by analyzing genomic deoxyribonucleic acid (DNA) in peripheral blood mononuclear cells is an attractive option. This analysis can be readily accomplished by amplifying a DNA fragment containing the factor V mutation site with polymerase chain reaction.

Prothrombin G20210A Mutation

In 1996, investigators from Leiden reported that a G-to-A substitution at nucleotide 20210 in the 3′-untranslated region of the prothrombin gene is associated with a 30% elevation of plasma prothrombin levels and an increased risk for venous thrombosis.[129] This mutation, which was discovered by directly sequencing the prothrombin gene of selected patients with venous thrombosis, is located in the 3′-untranslated region at the cleavage site for polyadenylation of prothrombin mRNA. The prothrombin G20210A mutation changes the position of the 3′-cleavage/polyadenylation reaction in prothrombin mRNA, thereby leading to increased prothrombin biosynthesis by the liver[130]; this finding contrasts with previous data indicating that the mutation changes mRNA stability by increasing mRNA 3′-end formation.[131]

Investigation of a referral population with a personal and family history of venous thrombosis demonstrated that 18% had the mutation in the 3′-untranslated region of the prothrombin gene, whereas it was present in only 1 of 100 healthy control subjects.[129] Among these patients with thrombosis, 40% also carried the factor V Leiden mutation, thus emphasizing the current view of venous thrombosis as a multigene disorder.

In the Leiden Thrombophilia Study, 6.2% of patients with venous thrombosis and 2.3% of healthy matched control subjects had the prothrombin gene mutation.[129] This mutation independently confers a 2.8-fold increased risk for venous thrombosis, and the effect is operative in both sexes and all age groups. Among heterozygotes with the prothrombin gene mutation, 87% of patients with thrombosis and control subjects in the study had prothrombin activity levels that were greater than 1.15 units/mL, whereas only 23% of those with a normal prothrombin genotype had levels elevated to this degree. A systematic review and meta-analysis of pediatric studies found that prothrombin gene mutation G20210A heterozygosity conferred an OR of 2.64 (95% CI, 1.60 to 4.41) for a first episode of venous thromboembolism and an OR of 1.88 (95% CI, 1.01 to 3.49) for recurrent VTE.[9] A similar analysis of cases of cerebral sinovenous thrombosis in children found that prothrombin mutation carriers had an OR for thrombosis of 1.95 (95% CI, 0.93 to 4.07).[101] An association with arterial ischemic stroke was also observed.[101]

In numerous other studies the prothrombin G20210A mutation has been documented to have a significantly higher frequency in patients with venous thrombosis than in healthy control subjects.[132-134] Large population studies have shown an overall prevalence of about 2% in the general white population, with significant geographic variation. In southern Europeans the prevalence is about 3%, but it was only very rarely identified in persons of Asian or African descent.

Polymerase chain reaction methods are used to detect the prothrombin G20210A mutation in genomic DNA.[129] Although plasma prothrombin activity and antigen levels are significantly higher in persons with the prothrombin G20210A mutation, prothrombin concentrations cannot be used to screen for the defect because of significant overlap with the normal population.[129,135]

HYPERHOMOCYSTEINEMIA

Homocysteine is a sulfur-containing amino acid involved in metabolic pathways that lead to the formation of other amino acids; methionine is generated through the remethylation of homocysteine or metabolized to cysteine via transsulfuration. The normal plasma homocysteine concentration is 5 to 16 µmol/L. Mild (16 to 24 µmol/L) or moderate (25 to 100 µmol/L) hyperhomocysteinemia has been identified as a seemingly independent risk factor for venous and arterial thrombotic events.[136-138] Hyperhomocysteinemia results from genetic and acquired abnormalities. The most common causes of acquired hyperhomocysteinemia are deficiencies of vitamin B_{12}, folate, or vitamin B_6, which are cofactors in homocysteine metabolism. A strong inverse correlation exists between hyperhomocysteinemia and folate levels and, to a lesser extent, with vitamin B_{12} and B_6 concentrations. Elderly patients frequently have elevated plasma homocysteine concentrations, even in the absence of vitamin deficiencies, as do patients with renal failure. Cigarette smoking is also associated with acquired hyperhomocysteinemia. The prevalence of hyperhomocysteinemia in the U.S. population has declined since the wheat supply was fortified with folic acid in the late 1990s. Patients with gluten sensitivity (as a result of celiac disease or other causes) may have mild hyperhomocysteinemia as a result of folate deficiency.

Homocystinuria is a rare autosomal-recessive inborn error of metabolism that presents in childhood. The most frequent cause is homozygous cystathionine β-synthase deficiency, which has a frequency in the general population of approximately 1 in 250,000. As a result of impaired intracellular metabolism of homocysteine, increased amounts of the amino acid (often >100 µmol/L) accumulate in blood and are excreted in urine. Children with homocystinuria exhibit premature atherosclerosis and arterial and venous thromboembolism, along with mental retardation, ectopic lenses, and skeletal abnormalities. The mechanisms by which hyperhomocysteinemia acts as an atherogenic and thrombogenic risk factor have been only partially elucidated.[139,140] Heterozygous cystathionine β-synthase deficiency is found in approximately 0.3% of the general population. Persons with heterozygous defects in this gene may have slightly elevated or even normal fasting plasma homocysteine levels. Testing 4 hours after an oral methionine load increases the sensitivity of this test.

In contrast to homocystinuria, a variant of methyltetrahydrofolate reductase (MTHFR) with an alanine-to-valine substitution at amino acid 222 (due to a C to T polymorphism at nucleotide 677) is common[141] and can be present in at least one copy in up to 61% of the population, depending on their origin, and homozygous in 1.4% to 15%.[138] This mutation causes thermolability of MTHFR and a 50% reduction in its specific activity. Defects in the remethylation pathway as a result of *MTHFR* gene defects or inadequate folate or vitamin B_{12} levels tend to cause elevated homocysteine levels under fasting conditions. The prevalence of hyperhomocysteinemia is almost twice as high when it is based on homocysteine measurements performed after methionine loading than when it is based on fasting levels. Genetic testing for the common C677T polymorphism in *MTHFR* is also possible. Because current data indicate that persons with mild hyperhomocysteinemia and a history of venous or arterial thrombosis should not be managed any differently from persons with normal homocysteine levels, justification no longer exists for routinely determining homocysteine levels or testing for *MTHFR* polymorphisms in such patients. In addition, results from the Leiden MEGA (Multiple Environmental and Genetic Assessment of Risk Factors for Venous Thrombosis) Study indicate that the presence of homozygosity for the *MTHFR* C677T polymorphism, which mildly increases homocysteine levels, is not associated with an increased risk for a first episode of venous thrombosis.[142] Although it was reported that hyperhomocysteinemia significantly increased the risk for a first venous thrombotic event in patients with the factor V Leiden mutation,[143] a meta-analysis of published studies found no additive or multiplicative interaction between these abnormalities for the risk of venous thrombosis.[144]

Because folic acid, vitamin B_6, and vitamin B_{12} supplementation can decrease plasma homocysteine levels, it was hypothesized that treatment with these supplements would reduce the risk for arterial and venous thrombosis. However, results of large randomized placebo-controlled clinical trials showed that clinical outcomes are not improved by providing supplements of these vitamins to patients with histories of ischemic stroke,[145] myocardial infarction,[146] vascular disease,[147] or venous thrombosis.[148]

DYSFIBRINOGENEMIAS

The dysfibrinogenemias are a heterogeneous group of disorders that may be asymptomatic or may be manifested as a bleeding diathesis or as recurrent venous or arterial thromboembolism. Qualitative fibrinogen abnormalities are inherited in an autosomal-dominant manner. A small number of variant fibrinogens have been reported to be associated with thrombotic complications. These defects can be detected with thrombin and reptilase times, which are often prolonged. Functional fibrinogen measurements are usually substantially lower than antigenic measurements in the plasma of affected patients. An occasional patient with dysfibrinogenemia may have a prolonged prothrombin time or PTT, and the inability of some abnormal fibrinogens to clot completely in vitro can result in false-positive results in fibrin(ogen) degradation product tests.

The functional and biochemical defects of a number of abnormal fibrinogens associated with thromboembolic disease have been characterized.[149,150] The conversion of fibrinogen to fibrin by thrombin results in the proteolytic cleavage of fibrinopeptides A and B from the molecule. Defects in the release of these two peptides[151-154] or abnormalities in fibrin polymerization[155-158] have been reported, although the link between these functional defects and thrombosis risk is unclear. Abnormalities in the binding of thrombin to fibrin have also been found in some dysfibrinogenemias.[159-162] In one of these kindreds, three homozygous siblings with a β-chain substitution of Ala by Thr at position 68 had a severe clinical phenotype and sustained both arterial and venous thrombosis at a young age.[161,163] It has been suggested that decreased binding of thrombin by this mutant fibrinogen may lead to the presence of excessive thrombin in the circulation and the occurrence of thrombosis.[163] Other fibrinogen mutants have been shown to cause abnormal fibrin polymerization.[155-157,160] Some abnormal fibrinogens have been evaluated for their ability to resist or promote fibrinolysis upon incorporation into a fibrin clot. The fibrin formed from fibrinogen “Chapel Hill III” has been demonstrated to be abnormally resistant to lysis by plasmin.[155] Activation of plasminogen is decreased in the presence of the fibrin formed from fibrinogen “Dusart” despite normal binding of tissue plasminogen activator to the substrate.[164-168] These abnormalities clearly have the potential for decreasing fibrinolytic activity in vivo, which results in a familial thrombotic diathesis in biochemically affected persons. The coexistence of factor V Leiden may predispose persons with certain dysfibrinogenemias to thromboembolism.[169]

INHERITED ABNORMALITIES OF DIMINISHED FIBRINOLYSIS

In contrast to the relationship between hyperfibrinolytic states and delayed, postprocedural bleeding, it is logical that diminished fibrinolytic activity may explain some cases of hereditary thrombophilia. Disorders of plasminogen activity or elevated plasminogen activator inhibitor–1 (PAI-1) function have been linked to thrombosis, whereas α_2-antiplasmin disorders have not been described in patients with thrombosis. Elevations in PAI-1 have been associated with arterial and atherothrombotic events in adults.[170] The 4G allele of the 4G/5G polymorphism in the promoter of the PAI-1 gene is associated with increased PAI-1 activity and was reported to be associated with a modest increase in thrombotic risk[171]; however, this association has not been confirmed.[172] The association between elevated PAI-1 activity and thrombosis have not been identified in pediatric patients.

Although investigators have identified a few persons with inherited abnormalities of the fibrinolytic mechanism and recurrent VTE, the clinical association is considerably less striking than that in many kindreds with deficiencies of AT, protein C, or protein S or with prothrombin gene mutation or APC resistance as a result of factor V Leiden mutation.

Dysplasminogenemia or hypoplasminogenemia has been reported in a number of persons with thromboembolic disease; the first case of an abnormal plasminogen was identified in Japan.[173] The propositus had a history of recurrent thrombosis, and family studies demonstrated that the biochemical abnormality followed an autosomal-dominant inheritance pattern. Despite the hereditary nature of the defect, none of the other biochemically affected members of the kindred had experienced a thrombotic event. Other Japanese pedigrees without thrombosis have since been described with the same biochemical defect; the gene frequency of this variant in the Japanese population was 0.018.[174] Population studies in the United States have not uncovered any cases of this dysplasminogenemia. The non-Japanese cases of dysplasminogenemia and hypoplasminogenemia have also been characterized by the absence of thrombotic episodes in biochemically affected family members other than the propositi.

Severe type 1 plasminogen deficiency is associated with a rare chronic inflammatory disease of the mucous membranes. Although this disorder can occasionally be life threatening, venous thrombosis was not observed in these patients. The disorder is characterized by the presence of fibrin-rich pseudomembranous lesions, and the most common clinical manifestations are ligneous conjunctivitis (80%) and ligneous gingivitis (34%); less common sites of involvement are the vagina, respiratory tract, ears, and gastrointestinal tract.[175] Patients with this disorder have been found to be homozygous or compound heterozygous for a number of different mutations in the plasminogen gene.[175] A severely affected infant with ligneous conjunctivitis has been treated successfully with a purified plasminogen concentrate,[176] but this product is not generally commercially available. The absence of thromboembolic events in persons with severe plasminogen deficiency and in most persons with hypoplasminogenemia and dysplasminogenemia supports the argument that diminished plasminogen function does not pose a significant thrombotic risk.

Some reports have documented the existence of thrombophilic families with impaired fibrinolysis.[177,178] Reevaluation of several of these families demonstrated the presence of hereditary protein S deficiency and no association between elevations in PAI-1 activity and a history of thrombosis.[179,180]

MANAGEMENT OF PATIENTS WITH INHERITED THROMBOTIC DISORDERS

Acute Thrombosis and Long-Term Management

When a patient with one of the inherited thrombotic disorders is discovered, family studies should be considered because approximately half the members of a given kindred may be affected. Institution of long-term anticoagulation is not generally recommended for persons who have not yet sustained thrombotic episodes, especially children. However, affected persons should receive counseling regarding the implications of the diagnosis and advice regarding the symptoms that require immediate medical attention. In women of childbearing age who have known hereditary thrombophilia, hormonal contraceptives are generally contraindicated in view of the increased thrombotic risk associated with the use of these medications. All thrombophilia carriers should be carefully evaluated before surgical, medical, or obstetric procedures that carry an increased thrombotic risk, and use of appropriate prophylactic anticoagulation regimens should be considered. In addition to prophylactic anticoagulation, nonpharmacologic preventive strategies should be discussed, along with relevant replacement of specific deficiencies with recombinant or concentrated products to raise plasma levels of the protein to the normal range during the perioperative period. In general, women with previous thrombotic episodes receive prophylactic heparin throughout pregnancy and asymptomatic women with thrombophilia are treated with either observation or heparin during the third trimester and in the postpartum period.

Management of an acute thrombotic event in patients with a hereditary thrombotic disorder is generally similar to that for patients who do not have an identifiable risk factor. Anticoagulant therapy generally consists of 3 to 6 months of heparin, low molecular weight heparin, or an oral vitamin K antagonist (e.g., warfarin). Warfarin is used less frequently in young children because of challenges in maintaining an international normalized ratio in the therapeutic range as a result of variable nutritional intake or other issues (e.g., compliance and malabsorption). Newer oral anticoagulants including dabigatran, rivaroxaban, and apixaban have not been adequately studied in children, although off-label use has begun following regulatory agency approval for the treatment and prevention of venous thromboembolism without the need for laboratory monitoring. The indications for thrombolytic therapy in patients with these disorders are similar to those in other patients who have had acute deep venous thrombosis or pulmonary embolism.

In adult patients with a first episode of symptomatic VTE, Prandoni and colleagues[181] found that the cumulative incidence of recurrent venous thrombosis after the cessation of anticoagulant therapy was 24.8% at 5 years and 30.3% at 8 years. Other investigators have confirmed that this risk is about 5% to 15% per year for the first several years after a first or even a second episode of unprovoked venous thrombosis. In children, first-year recurrence rates for VTE are reported to be 8%, with this rate rising to 18% in subsequent years.[182,183,184] Inherited thrombophilia can increase recurrence rates further in children, with the exception of the factor V Leiden and prothrombin gene mutations (discussed later). Recurrences are less common when the initial event is associated with a transient risk factor (e.g., surgery, trauma, or pregnancy). Despite the relatively high recurrence risk in patients with a first episode of unprovoked venous thrombosis, anticoagulation has not proved to have sufficient benefit in excess of known bleeding risk to support long-term prophylaxis for all patients who are at substantial risk for recurrence. For example, one controlled trial evaluated the efficacy of long-term warfarin therapy (international normalized ratio of 2 to 2.85) for 6 months or indefinitely in 227 patients who had a second venous thrombotic episode, but who had not specifically inherited thrombophilia.[185] Long-term use of warfarin was highly effective in preventing recurrences when compared with 6 months of therapy (2.6% vs. 21% over a period of 4 years); this benefit was partially counterbalanced by a trend toward an increased incidence of major hemorrhage (8.6% vs. 2.3%), and no difference in mortality rate was found between the two groups. Persistent elevation of factor VIII and/or D-dimer 1 month after cessation of anticoagulation is a risk factor for thrombosis recurrence in pediatric patients, whether familial or acquired.[182]

Because of the relatively high frequency of the factor V Leiden mutation in adult patients who have a first episode of VTE, a substantial amount of data is available on the risk of recurrence. Although two groups of investigators initially reported that patients with the factor V Leiden mutation who had a first venous thrombotic event were more than twice as likely to have a recurrent episode compared with persons who did not have the mutation,[143,186] several other groups have not found that heterozygosity for this defect or the prothrombin G20210A mutation confers a higher risk for recurrence.[187-191] Thus the consensus view is that neither of these defects alone is predictive of recurrence, and authors of several studies have argued that long-term warfarin therapy should not be used after a first thromboembolic episode in these patient populations. No increase in mortality has been observed among patients with the factor V Leiden mutation.[192] The recurrence risk appears to be significantly higher in the small subset of patients who are heterozygous for two hereditary prothrombotic defects or homozygous for factor V Leiden.[107-110,190,193]

As a result of the relatively low frequency of AT, protein C, or protein S deficiency in unselected cohorts who have an initial episode of VTE, randomized clinical trials have included too few patients with these deficiencies to draw firm conclusions. A literature review and retrospective cohort study suggested that they have a high annual incidence of recurrent VTE during the years immediately after a first episode and that this incidence declines thereafter.[194] Retrospective studies are unable to demonstrate an increase in mortality in patients with AT[195] or protein C deficiency.

For the individual adult patient, the decision to continue anticoagulation indefinitely requires estimation of the quantitative risk over time for recurrent thrombosis (including fatal pulmonary embolism) and major bleeding (including fatal bleeding). The approach to pediatric patients involves additional considerations. Pediatric patients have lower rates of thrombosis and recurrent thrombosis than do adults. Although children may be less predisposed to bleeding events from anatomic lesions (e.g., ulcers and diverticulosis) than are older adults, adolescents often display risk-taking behaviors and are prone to accidental trauma, increasing their risk of bleeding while they take anticoagulation agents. Patient compliance has a major impact on the success of therapy, and patient preferences and behaviors must be factored into the decision. Because future events in a patient with only one previous thrombotic episode cannot currently be accurately predicted and there is a finite risk of bleeding associated with indefinite anticoagulation therapy, recommendations regarding long-term anticoagulation are individualized. The following clinical features should be considered when making this decision:

1. **The number, sites, and severity of thrombosis.** A patient who previously sustained a massive pulmonary embolism is more likely to receive long-term anticoagulation than is a subject in whom deep venous thrombosis developed in a calf vein unless the patient has symptoms or signs of a significant postphlebitic syndrome.
2. **Whether the thrombotic episodes were spontaneous or whether precipitating factors were present.** If a

precipitating event such as a major abdominal operation was a factor when the initial venous thrombotic event occurred, the risk of recurrence is substantially lower than if the event was spontaneous, and the patient does not require long-term anticoagulation after the initial episode is adequately treated and the precipitating factor is removed.

3. **The patient's risk of bleeding while receiving anticoagulation.** A history of bleeding or risk-taking behaviors or difficulty maintaining therapeutic anticoagulation because of altered gastrointestinal function will lead to an increased risk for bleeding.
4. **The lifestyle of the individual.** Situations that may influence the decision to recommend long-term anticoagulation include occupations that entail prolonged periods of immobilization and therefore might be associated with an increased risk for thromboembolism, jobs with a higher than average chance of trauma that might lead to thrombotic or bleeding complications, or both. Gender may influence the choice of anticoagulant, because warfarin is generally contraindicated in pregnancy.
5. **A history of thromboembolism in other biochemically affected members of the family with an inherited thrombotic disorder.** Although marked intrafamilial and interfamilial heterogeneity has been observed in the phenotypic expression of inherited thrombotic disorders, it is reasonable for biochemically affected patients from severely affected kindreds with a single thrombotic episode to consider indefinite anticoagulation therapy.

In pediatric patients, "indefinite" anticoagulation therapy is often discussed and reevaluated annually. Given the cumulative bleeding risk through the remainder of childhood, adolescence, young adulthood, and beyond, indefinite anticoagulation therapy is not commonly used in pediatric patients. In their 2012 guidelines, the American College of Chest Physicians suggest consideration of ongoing anticoagulation in pediatric patients who have recurrent idiopathic thrombosis or thrombosis with an ongoing risk factor.[196] The impact of thrombophilia on this discussion in pediatrics is unclear and considered individually.

Antithrombin Deficiency

Non–heparin-based anticoagulants are often used for long-term anticoagulation for patients who have AT deficiency. However, patients with AT deficiency can usually be treated successfully with intravenously administered heparin,[197] although in some situations unusually high doses of the drug are required to achieve adequate anticoagulation. In patients with AT deficiency who are receiving heparin for the treatment of acute thrombosis, the adjunctive role of AT supplementation is not clearly defined because controlled trials have not been performed.[197] Two AT products are available: a concentrate purified from human plasma and a recombinant human AT purified from the milk of transgenic goats.[198] AT replacement should be considered in patients who have difficulty achieving adequate heparinization or if recurrent thrombosis is observed despite adequate anticoagulation. It is also reasonable to treat subjects who are deficient in AT with concentrate before major surgery or in obstetric situations in which the risks of bleeding from anticoagulation are unacceptable. The manufacturing processes used to prepare AT concentrate result in a product that is greater than 95% pure; they also inactivate hepatitis B virus and human immunodeficiency virus type 1.[199,200] Hence it is preferable to administer AT concentrate rather than fresh-frozen plasma.

The biologic half-life of AT is approximately 48 hours.[14] Infusion of 50 units of plasma-derived AT concentrate per kilogram of body weight (1 unit is defined as the amount of AT in 1 mL of pooled normal human plasma) will usually raise the plasma AT level to approximately 120% in a congenitally deficient person with a baseline level of 50%.[200-204] Plasma levels should be monitored to ensure that they remain higher than 80%; administration of 60% of the initial dose at 24-hour intervals is recommended to maintain inhibitor levels in the normal range.[204] Recombinant AT is administered as an infusion after a loading dose to target plasma AT levels between 80% to 120%.

Coumarin-Induced Skin Necrosis

Because coumarin-induced skin necrosis is a rare complication, therapy has been guided primarily by knowledge regarding its pathogenesis. The diagnosis should be suspected in patients with painful, red skin lesions that develop within a few days after initiation of the drug, and immediate intervention is required to prevent rapid progression and reduce complications. Therapy should consist of immediate discontinuation of warfarin, administration of vitamin K, and infusion of heparin at therapeutic doses. However, lesions have been reported to progress despite adequate anticoagulation with heparin. In patients with hereditary protein C deficiency, administration of a source of protein C should be given serious consideration, and it may also be appropriate in other patients with coumarin-induced skin necrosis because they invariably have reduced plasma levels of functional protein C when the skin lesions first appear. Fresh-frozen plasma has been used, but improved results can be expected after the administration of a highly purified protein C concentrate, which facilitates rapid and complete normalization of plasma protein C levels.[205]

Because of the infrequent occurrence of coumarin-induced skin necrosis, it may be advisable to take special precautions when initiating warfarin in a patient who is previously known or likely to have protein C deficiency. Warfarin should be started only when the patient is fully heparinized, and the dose of the drug should be increased gradually, starting at a relatively low level. Patients with heterozygous protein C deficiency and a history of warfarin-induced skin necrosis have been successfully retreated with warfarin, although the emergence of alternative anticoagulants may reduce reexposure to warfarin. Protein C administration either in the form of fresh-frozen plasma or protein C concentrate provides protection against the development of recurrent skin necrosis until a stable level of anticoagulation is achieved.[58,206]

Homozygous or Doubly Heterozygous Protein C Deficiency and Neonatal Purpura Fulminans

Management of neonatal purpura fulminans in association with homozygous or doubly heterozygous protein C deficiency is complicated, and neither heparin therapy nor antiplatelet agents have been shown to be effective.[67,69-73] Administration of a protein C source appears to be critical in the initial treatment of these patients. Fresh-frozen plasma has been used successfully to treat these infants. However, the half-life of protein C in the circulation is only about 6 to 16 hours,[47,207] and frequent administration of plasma is limited by the development of hyperproteinemia or hypertension, loss of venous access, and the potential for exposure to infectious viral agents. A highly purified concentrate of protein C has been developed and is efficacious in treating neonatal purpura fulminans.[208] Warfarin has been administered to these infants without the redevelopment of skin necrosis during the phased withdrawal of fresh-frozen plasma infusions,[67,72,74,209,210] and this medication has been used on a long-term basis to control the thrombotic diathesis. A 20-month-old child with liver failure and homozygous protein C deficiency successfully underwent liver transplantation, which normalized his protein C levels and resolved the thrombotic diathesis.[211]

Evaluation of Relatives of Patients with Hereditary Thrombophilia

Family history is an essential component of the evaluation of patients with thrombotic complications and often influences the decision to test for hereditary risk factors. Pediatric hematologists/oncologists are frequently asked whether to screen a pediatric patient because of identification of a family member with thrombophilia or whether to screen other family members after thrombophilia is identified in a pediatric patient. Appropriate testing of the patient with thrombosis is important, but screening asymptomatic children who have not experienced thrombophilic events is generally not recommended. Equipoise exists with regard to whether to screen family members of probands who have a history of thrombosis unless there is a very strong history of VTE. In a study of 192 kindreds with a member homozygous for either the factor V Leiden or prothrombin gene mutation, the incidence of VTE was higher in affected relatives when the symptomatic proband was heterozygous for either mutation rather than being homozygous.[212] A study of 533 family members of 206 children with VTE identified a ninefold higher risk of thrombosis in family members with hereditary thrombophilia compared with probands who did not have a defect; the risk was highest in patients with deficiencies of AT, protein C, or protein S.[213] The type of thrombophilia and family history should therefore guide counseling for individual families. However, caution should be exercised in providing false reassurance to family members who test negative and in providing overly aggressively anticoagulation for asymptomatic persons who test positive.

This meta-analysis of observational studies of children with arterial ischemic stroke or cerebral sinovenous thrombosis demonstrates an association with thrombophilia and cerebral thrombosis, both arterial and venous, in children.

102. Middeldorp S, Meinardi JR, Koopman MM, et al: A prospective study of asymptomatic carriers of the factor V Leiden mutation to determine the incidence of venous thromboembolism. *Ann Intern Med* 135:322–327, 2001.

This prospective study of factor V Leiden carriers without thrombosis demonstrates a low annual incidence of thrombosis (0.58% overall), raising questions about the utility of screening asymptomatic family members.

129. Poort SR, Rosendaal FR, Reitsma PH, et al: A common genetic variation in the 3′-untranslated region of the prothrombin gene is associated with elevated prothrombin levels and an increase in venous thrombosis. *Blood* 88:3698–3703, 1996.

This article provides the first description of the prothrombin gene mutation G20210A as a thrombotic risk factor.

142. Bezemer ID, Doggen CJ, Vos HL, et al: No association between the common MTHFR677C→T polymorphism and venous thrombosis: results from the MEGA study. *Arch Intern Med* 167:497–501, 2007.

This study refutes the role of the most common methyltetrahydrofolate reductase polymorphism as a risk factor for venous thrombosis.

145. Toole JF, Malinow MR, Chambless LE, et al: Lowering homocysteine in patients with ischemic stroke to prevent recurrent stroke, myocardial infarction and death. The vitamin intervention for stroke prevention (VISP) randomized controlled trial. *JAMA* 291:565–575, 2004.

This study showed that B vitamin supplementation for the treatment of hyperhomocysteinemia did not reduce the risk of recurrent arterial thromboembolic disease.

172. Ridker PM, Hennekens CH, Lindpaintner K, et al: Arterial and venous thrombosis is not associated with the 4G/5G polymorphism in the promoter of the plasminogen activator inhibitor gene in a large cohort of US men. *Circulation* 95:59–62, 1997.

This study, which used data from the Physicians' Health Study, failed to confirm the association of plasminogen activator inhibitor–1 (PAI-1) 4G/5G promoter polymorphism with thrombotic risk and discourages testing for this polymorphism as a surrogate for PAI-1 activity.

182. Goldenberg NA, Knapp-Clevenger R, Manco-Johnson MJ, et al: Elevated plasma factor VIII and D-dimer levels as predictors of poor outcomes of thrombosis in children. *N Engl J Med* 351:1081–1088, 2004.

This study shows that persistent elevations of factor VIII activity or D-dimer levels predict poor outcomes after thrombosis in children.

183. Monagle P, Adams M, Mahoney M, et al: Outcome of pediatric thromboembolic disease: a report from the Canadian Childhood Thrombophilia Registry. *Pediatr Res* 47:763–766, 2000.

Utilizing a large Canadian repository of data regarding pediatric thrombosis and thrombophilia, these authors performed the largest study of outcomes after thrombosis in children thus far, with findings showing a 2.2% rate of thrombosis-related mortality, a 12.4% rate of postthrombotic syndrome, and a 8.1% rate of first-year recurrence.

196. Monagle P, Chan AK, Goldenberg NA, et al: Antithrombotic therapy in neonates and children: Antithrombotic Therapy and Prevention of Thrombosis, 9th ed: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines. *Chest* 141(Suppl 2):e737S–e801S, 2012.

This current edition of evidence-based practice guidelines for the management of pediatric thrombosis combines an excellent summary of available evidence with expert consensus advice when evidence is not available.

212. Bucciarelli P, De Stefano V, Passamonti SM, et al: Influence of proband's characteristics on the risk for venous thromboembolism in relatives with factor V Leiden or prothrombin G20210A polymorphisms. *Blood* 122:2555–2561, 2013.

This study of 192 kindreds with homozygous inherited thrombophilia found risk to relatives only when the proband was heterozygous and sustained a venous thromboembolic event, in contrast with the study in reference 102, which found no risk when probands are heterozygotes without thrombosis.

213. Holzhauer S, Goldenberg NA, Junker R, et al: Inherited thrombophilia in children with venous thromboembolism and the familial risk of thromboembolism: an observational study. *Blood* 120:1510–1515, 2012.

This study of 533 family members of 206 children with inherited thrombophilia found an increased risk of thrombosis in family members of probands with inherited deficiency of antithrombin, protein C, or protein S (2.82%), but not for factor V Leiden (0.25%) or prothrombin gene mutation (0.42%) compared with control subjects (0.10%).

CHAPTER OUTLINE

QUANTITATIVE PLATELET ABNORMALITIES
Thrombocytopenia
Thrombocytosis

ACQUIRED DEFECTS IN PLATELET FUNCTION
Drug-Induced Platelet Dysfunction
Platelet Abnormalities Associated with Systemic Diseases

Platelets play a critical role in hemostasis. When the vascular endothelium is disrupted, platelets adhere to the subendothelium and initiate primary hemostasis. The details of normal platelet physiology and function are presented in Chapter 26. Excessive bleeding occurs if primary hemostasis is abnormal because platelets are either deficient in number or defective in function. Acquired platelet defects, both quantitative and qualitative, are discussed in this chapter, and the corresponding inherited disorders are discussed in Chapter 30.

The normal circulating platelet count for all ages ranges from 150,000 to 400,000/μL. Circulating platelets constitute two thirds of total body platelets; the remaining platelets are located within the spleen.[1] Platelets exhibit marked heterogeneity in size. Two factors have been proposed to account for this heterogeneity.[2] First, as platelets age, they may become smaller as a result of fragmentation or loss of granule contents or membrane proteins. Second, megakaryocytes produce platelets of varying size. In thrombolytic states megakaryocytes preferentially produce large platelets, a phenomenon analogous to stress erythropoiesis.[2] The average life span of platelets is 7 to 10 days, although survival of transfused platelets in a thrombocytopenic recipient is reduced proportionately to the severity of the thrombocytopenia.[3] These findings suggest either that there is increased platelet utilization in thrombocytopenic states or that a fixed number of platelets are removed from the circulation each day, irrespective of the platelet count.[4]

QUANTITATIVE PLATELET ABNORMALITIES

Thrombocytopenia

The clinical manifestations of thrombocytopenia typically involve the skin or mucous membranes and include petechiae, ecchymoses, prolonged bleeding at incision or venipuncture sites, epistaxis, gastrointestinal hemorrhage, hematuria, and menorrhagia. Intracranial hemorrhage (ICH) may occur but is rare. As discussed in Chapter 29, the deep muscle hematomas and hemarthroses typically seen in individuals with deficiencies of factor VIII or factor IX generally do not occur with platelet disorders. Causes of thrombocytopenia fall into three broad categories: platelet sequestration (usually in the spleen), increased platelet destruction, and decreased platelet production. The differential diagnosis of thrombocytopenia in children is outlined in Box 34-1. Discriminating among these diagnoses is important because the cause of thrombocytopenia affects the choice of therapy.

When a patient with thrombocytopenia is assessed, the risk of bleeding episodes should be estimated. If the risk is significant, treatment is warranted. Unfortunately, there is a lack of direct correlation between the platelet count and the risk of bleeding episodes, which confounds treatment decisions. The risk of hemorrhage is affected by many factors, such as coexisting coagulation defects, trauma, and surgery. In older children and adults, serious spontaneous bleeding does not occur until the platelet count is less than 20,000/μL. Many physicians use a platelet count of 10,000 to 20,000/μL as the threshold for intervention. This threshold was derived from a study of children with leukemia and may not be relevant for all cases of thrombocytopenia. For example, because of the increased risk for ICH in neonates, a threshold of 20,000 to 50,000/μL is often used. In addition, patients with a defect in production are more likely to have serious bleeding than those with a destructive platelet problem because in the latter patients, platelets tend to be larger and more functional.

Box 34-1 **Differential Diagnosis of Thrombocytopenia in Children and Adolescents**

DESTRUCTIVE THROMBOCYTOPENIAS

PRIMARY PLATELET CONSUMPTION SYNDROMES

- Immune thrombocytopenias
  - Acute and chronic ITP
  - Autoimmune diseases with chronic ITP as a manifestation
    - Cyclic thrombocytopenia
    - ALPS and its variants
    - SLE
    - Evans syndrome
    - Antiphospholipid antibody syndrome
    - Neoplasia-associated immune thrombocytopenia
  - Thrombocytopenia associated with HIV
  - Neonatal immune thrombocytopenia
    - Alloimmune
    - Autoimmune (e.g., maternal ITP)
  - Drug-induced (including HIT)
  - Posttransfusion purpura
  - Allergy and anaphylaxis
- Nonimmune thrombocytopenias
  - Thrombocytopenia of infection
    - Bacteremia or fungemia
    - Viral infection
    - Protozoan infection
  - Thrombotic microangiopathic disorders
    - TTP
    - HUS
    - BMT–associated microangiopathy
    - Drug-induced
  - Platelets in contact with foreign material
  - Congenital heart disease
  - Drug-induced via direct platelet effects (ristocetin, protamine)
  - Type 2b VWD or platelet-type VWD

COMBINED PLATELET AND FIBRINOGEN CONSUMPTION SYNDROMES

- DIC
- Kasabach-Merritt syndrome
- HLH

IMPAIRED PLATELET PRODUCTION

- Hereditary disorders (see Chapter 30)
- Acquired disorders
  - Aplastic anemia
  - MDS
  - Marrow infiltrative process
  - Nutritional deficiency states (Fe, folate, vitamin B_{12}, anorexia nervosa)
  - Drug- or radiation-induced thrombocytopenia
  - Neonatal hypoxia or placental insufficiency

SEQUESTRATION

- Hypersplenism
- Hypothermia
- Burns

ALPS, Autoimmune lymphoproliferative syndrome; *BMT,* bone marrow transplant; *DIC,* disseminated intravascular coagulation; *HLH,* hemophagocytic lymphohistiocytosis; *HIT,* heparin-induced thrombocytopenia; *HIV,* human immunodeficiency virus; *HUS,* hemolytic-uremic syndrome; *ITP,* immune thrombocytopenic purpura; *MDS,* myelodysplastic syndrome; *SLE,* systemic lupus erythematosus; *TTP,* thrombotic thrombocytopenic purpura; *VWD,* von Willebrand disease.

Thrombocytopenia Reflecting Laboratory Artifact or Sequestration

Spurious Thrombocytopenia. Thrombocytopenia may be an incidental finding. If the history and physical examination do not suggest a defect in primary hemostasis, a low platelet count may represent a laboratory artifact. Potential causes of a falsely low platelet count include platelet activation during blood collection, undercounting of megathrombocytes,[5] or pseudothrombocytopenia as a result of in vitro agglutination by ethylenediaminetetraacetic acid (EDTA)-dependent antibodies.[6] In a patient with artifactual thrombocytopenia, large clumps of agglutinated platelets may be found at the periphery of the blood film, or platelets may be adherent to leukocytes and form platelet "satellites" (Fig. 34-1).[7]

Pseudothrombocytopenia secondary to EDTA-dependent antibodies can be confirmed by repeating the platelet count with another anticoagulant (e.g., citrate, oxalate, heparin) or by preparing a blood film directly from a finger- or heel-puncture sample. The cause of EDTA-associated pseudothrombocytopenia is an immunoglobulin G (IgG) or immunoglobulin M (IgM) directed against a cryptic platelet antigen exposed only in the presence of this anticoagulant.[6] The phenomenon is not associated with any particular pathology and may be observed in both healthy subjects and patients with diseases. In some individuals the antibodies responsible persist indefinitely, whereas in others the antibodies are transient. No abnormalities in hemostasis or thrombosis have been reported in any of these patients.

Other causes of pseudothrombocytopenia include drugs[8] and EDTA-independent cold agglutinins.[9] The overall incidence of pseudothrombocytopenia in hospitalized adult patients is approximately 1%, but it is less common in pediatric patients.[6] No further evaluation or treatment is indicated for a patient documented as having a spuriously low platelet count.

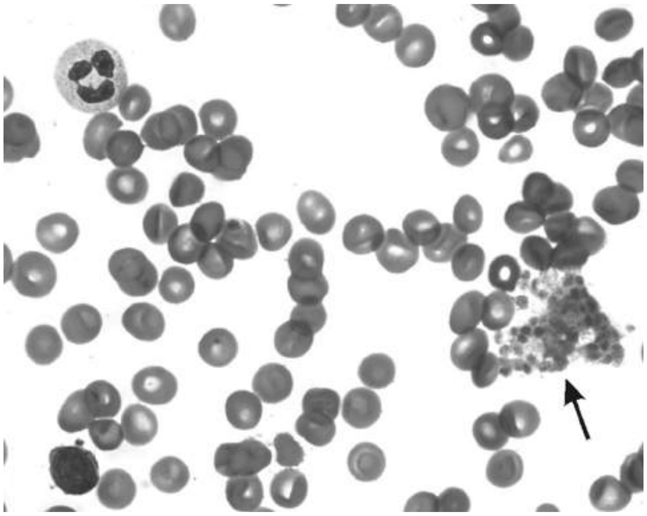

Figure 34-1 Pseudothrombocytopenia: photomicrograph of EDTA–dependent platelet clumping *(arrow)*.

Apparent Thrombocytopenia Caused by Hypersplenism. The spleen normally retains about a third of the body's platelets in an exchangeable pool.[1] The fraction of platelets sequestered in the spleen increases in proportion to spleen size. Thus an apparent thrombocytopenia can result from increased pooling in an enlarged spleen—a condition referred to as *hypersplenism*. In patients with hypersplenism, recovery of transfused autologous platelets is only 10% to 30%, whereas in normal individuals it is 60% to 80% and in asplenic patients it is 90% to 100%. Splenic blood flow is the major determinant of the size of the exchangeable splenic platelet pool in splenomegalic states.[10] Administration of intravenous epinephrine causes constriction of the splenic artery and results in passive emptying of platelets into the circulation. This increase in platelet count is proportionately greater in patients with splenomegaly than in normal subjects.

In general, the apparent thrombocytopenia that results from pooling in an enlarged spleen is mild (50,000 to 150,000/μL). Platelet counts of less than 50,000/μL should not be attributed to splenomegaly alone without further investigation. The degree of hypersplenism is proportional to spleen weight, whether the splenomegaly is due to congestion (e.g., cirrhosis with portal hypertension), hemolytic anemia (e.g., hemoglobin SC disease), or other causes. Because thrombocytopenia secondary to splenic pooling is not usually clinically important, no treatment is warranted, although splenectomy may be indicated for patients with severe thrombocytopenia, as can occur in Gaucher disease or other storage diseases.

Apparent Thrombocytopenia Caused by Hypothermia. Platelets are transiently sequestered in the spleen, liver, and other organs of experimental animals subjected to hypothermia. On rewarming of the animal, these platelets return to the circulation. A similar phenomenon has been observed in hypothermic patients. Transient thrombocytopenia (platelet counts of 7000 to 62,000/μL) has been reported in hypothermic patients of various ages.[11,12] Less significant thrombocytopenia has been observed in patients undergoing cardiac surgery with hypothermic perfusion. Treatment of the thrombocytopenia associated with hypothermia consists of rewarming and documentation of return of the platelet count to the normal range, which usually occurs in 4 to 10 days.

Thrombocytopenia Caused by Increased Platelet Destruction

A major etiologic classification of acquired thrombocytopenia of childhood is increased platelet destruction. Clinical conditions associated with increased platelet destruction are listed in Box 34-1. These conditions can be further subgrouped into immune and nonimmune causes.

Immune Thrombocytopenias. Autoantibodies, alloantibodies, or drug-dependent antibodies may associate with platelet membranes and target the cells for accelerated destruction by phagocytes of the reticuloendothelial system. An antibody mediating immune destruction of platelets may be directed against a platelet membrane antigen, or it may be part of an immune complex that binds Fc receptors on platelets.

Platelet antigens fall into two general classes. Glycoproteins that occur predominantly on platelets, such as the glycoprotein IIb/IIIa (GPIIb/IIIa) or GPIb/IX/V complexes, are often termed *platelet-specific antigens*. The glycoproteins (e.g., human leukocyte antigen [HLA] class I) and glycolipids (e.g., blood group ABH antigens) expressed on platelets, leukocytes, and other cell types are termed *platelet-nonspecific antigens*. Antibodies against platelet-specific and platelet-nonspecific antigens are responsible for a number of clinical syndromes, including autoimmune thrombocytopenia, neonatal alloimmune thrombocytopenia (NAIT), posttransfusion purpura (PTP), and platelet transfusion refractoriness. Antibodies directed against platelet integrins are common in immune thrombocytopenias. For example, autoantibodies directed against GPIIb/IIIa are seen in immune thrombocytopenic purpura (ITP)[13,14] and in drug-induced thrombocytopenia.[15,16] Several clinically significant alloantigens are located on GPIIb/IIIa, including HPA-1a, the human platelet antigen most frequently implicated in NAIT (discussed later). Autoantibodies against GPIb or GPIX also have been reported in patients with ITP[13,14] and drug-induced thrombocytopenia.[15,17]

HLA class I antigens are expressed on a wide range of cells, including platelets, and are important for the recognition of self by cytotoxic T cells. HLA-A and HLA-B antigens are strongly expressed on platelets.[18] Alloantibodies against HLA-A or HLA-B antigens frequently form in multiparous women and multiply transfused patients, and these alloantibodies contribute to platelet transfusion refractoriness. HLA-C antigens are weakly expressed on platelets and are far less likely to induce alloantibodies, thus making it less necessary to match the HLA-C locus for donor-recipient compatibility in platelet transfusions. HLA class II antigens, which function in antigen presentation by macrophages and B lymphocytes, are not expressed on platelets.

ABH blood group antigens are carried on a number of platelet glycoproteins, including the GPIIb/IIIa and GPIb/IX/V complexes.[19] ABH antigens are also expressed on glycolipids.[19] In rare instances these antigens have been implicated as the cause of immune-mediated platelet destruction, but in general these platelet-nonspecific antigens play only a minor role in immune thrombocytopenias.

Platelet Antibody Testing. A large number of assays have been developed to detect antibodies directed against or associated with platelet membrane antigens.[20] These assays can be categorized into direct (detecting antibody associated with the patient's platelets) or indirect (detecting antibody in the patient's serum that binds to control platelets). Indirect tests may detect, in addition to autoantibodies, alloantibodies (e.g., HLA related), particularly in multiparous women and individuals who have received multiple transfusions, and thus give false-positive results. Autoantibodies tend to be associated with the patient's platelets and are usually present in low concentration in serum. Therefore a direct test is the preferred test for autoimmune thrombocytopenias such as ITP.[20]

A number of direct assays measure immunoglobulin on platelets, regardless of whether the immunoglobulin

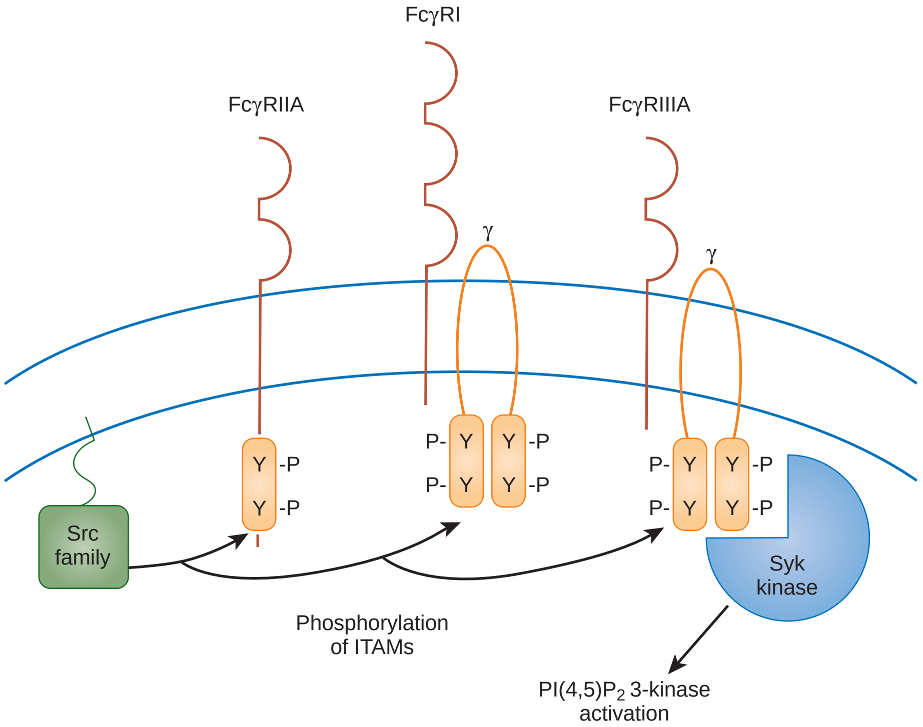

Figure 34-2 Activating Fcγ receptors on macrophages. Fcγ receptors signal phagocytosis via their phosphorylated ITAM (immunoglobulin gene–related tyrosine activation motif) domains. Receptor cross-linking stimulates src family kinases to phosphorylate tyrosine (Y) residues within the ITAM domain of FcγRIIA or within the dimerized γ subunits of FcγRI or FcγRIIIA. The tyrosine kinase syk is then recruited to the phosphorylated ITAM domains and activated. Syc mediates phagocytosis by activating phosphatidylinositol 3-kinase and phospholipase C. PI(4,5)P_2, phosphatidylinositol 4,5-bisphosphate. *(Modified from Aderem A, Underhill DM: Mechanisms of phagocytosis in macrophages.* Annu Rev Immunol *17:595, 1999.)*

is specifically or nonspecifically bound to the platelet surface. These assays generally detect platelet-associated IgG (PAIgG), but they can also be engineered to detect IgM or IgA. PAIgG is increased in immune disorders such as ITP and in nonimmune thrombocytopenic disorders such as leukemia and myelodysplastic syndrome. Thus the specificity of these tests is limited. Moreover, the sensitivity of these tests is limited because autoantibodies, such as those responsible for ITP, represent only a small fraction of the total PAIgG. Megakaryocytes nonspecifically take up plasma proteins, including IgG and albumin, and incorporate these proteins into the alpha granules of platelets, especially in disease states associated with increased thrombopoiesis.[21] Therefore increased PAIgG can result from elevated antibody production for any reason.

More recent assays use antigen capture techniques to detect platelet glycoprotein–specific antibodies, such as those that recognize GPIIb/IIIa and GPIa/IX/V, and have high specificity. Unfortunately, the sensitivity is generally too low for these assays to be used for the routine serologic diagnosis of most immune thrombocytopenias.[20] A newer method is based on flow cytometric detection of autoantibodies reacting with specific platelet proteins immobilized on microbeads.[22]

Macrophage and Platelet Fcγ Receptors. Receptors for the Fc domain of IgG (Fcγ receptors) are found on a variety of cell types, including macrophages and platelets. These receptors have been shown to play a critical role in immune complex–mediated platelet destruction. Fcγ receptors are diverse in structure and function and fall into two major classes: those that activate effector functions, such as phagocytosis or platelet activation, and those that inhibit effector functions.[23]

Activating Fcγ receptors on macrophages include the low-affinity receptors FcγRIIA and FcγRIIIA and the high-affinity receptor FcγRI (Fig. 34-2).[23] As discussed later, cross-linking of the activating receptor FcγRIII promotes phagocytosis of antibody-coated platelets in certain disease states, including ITP. The only Fcγ receptor expressed on platelets is the activating receptor FcγRIIA. Binding of IgG complexes to this receptor results in receptor cross-linking, which in turn initiates platelet aggregation and activation. This process is involved in heparin-induced thrombocytopenia (HIT), the most common drug-induced thrombocytopenia.

Immune Thrombocytopenic Purpura. ITP is a disorder characterized by accelerated destruction of antibody-sensitized platelets by phagocytic cells, especially those of the spleen. In many affected individuals, inhibition of megakaryopoiesis also contributes to the degree of thrombocytopenia. ITP is the most common autoimmune disorder affecting a blood element. The annual incidence is about 1 in 10,000 children. Two major forms are seen: acute ITP and chronic ITP. Acute ITP is usually a benign, self-limited condition that occurs in young children, typically those younger than 10 years. Often a viral infection or vaccination precedes the onset of acute ITP. In most of these patients, the thrombocytopenia resolves within weeks or a few months of the original manifestation. Chronic ITP is defined arbitrarily as persistence of thrombocytopenia (platelet count <150,000/μL) for longer than 6 months after the initial manifestation, although some hematologists advocate a later cutoff point (Box 34-2).

Box 34-2 **Controversial Issues Involving Immune Thrombocytopenic Purpura**

CONTROVERSIAL ISSUE 1

What is the definition of chronic ITP? Traditionally, chronic ITP has been defined as thrombocytopenia lasting longer than 6 months. Many pediatric hematologists take exception to this definition because a significant fraction of children with ITP recover in 6 to 12 months. The Intercontinental Childhood ITP Study Group has recommended that a 12-month rather than a 6-month cutoff point be used to define chronicity.[24]

CONTROVERSIAL ISSUE 2

Is it necessary to perform bone marrow aspiration in patients with suspected ITP before starting glucocorticoid therapy? Although the diagnosis of leukemia is extremely unlikely when the clinical history, physical examination, and peripheral smear are consistent with ITP, many hematologists routinely perform bone marrow aspiration before initiating glucocorticoid therapy. Retrospective studies[25-27] suggest that this may not be necessary. Bone marrow aspiration or biopsy is warranted for children with atypical laboratory features and for those in whom initial therapy fails.

CONTROVERSIAL ISSUE 3

Where does splenectomy belong in the therapeutic decision tree for chronic ITP? Experts generally agree that splenectomy should be deferred as long as possible and be reserved for patients with severe, symptomatic thrombocytopenia. The favorable safety profile of rituximab and the possibility of a sustained response could justify its use instead of splenectomy in the decision tree, but this has yet to be demonstrated in a prospective clinical trial. Despite the invasive and irreversible nature of splenectomy, some pediatric hematologists advocate the use of rituximab only after splenectomy has failed because splenectomy has a superior 5-year response rate compared with rituximab (71% versus 26%).

ITP, Immune thrombocytopenic purpura.

Children in whom ITP is diagnosed have an excellent chance of spontaneous recovery, irrespective of therapy. The platelet count returns to normal in 4 to 8 weeks in approximately half of the patients and by 3 months after diagnosis in two thirds of children.[28] In a review[29] of 12 publications involving more than 1500 children with ITP, 76% achieved complete remission within 6 months of initial evaluation. Spontaneous recovery was documented in 37% of the remaining patients with thrombocytopenia persisting longer than 6 months. These findings have been confirmed in other large studies.[24,30] Factors associated with the development of chronic ITP include age older than 10 years, insidious onset, and female gender.[30]

Pathogenesis. ITP is caused by autoantibodies that interact with membrane glycoproteins on the surface of platelets and megakaryocytes. These antibodies result in accelerated platelet destruction and may also impair thrombopoiesis. More than a third of adults with ITP have inadequate platelet production despite increased numbers of megakaryocytes in their bone marrow.[31] Certain antiplatelet antibodies have been shown to inhibit megakaryocytopoiesis or egress of platelets from the marrow space.[32,33] The GPIIb/IIIa complex is the autoantigen implicated most often as the cause of childhood and adult ITP.[14] Autoantibodies directed against the GPIb/IX/V and GPIa/IIa complexes have also been reported.[34] In rare instances platelet glycolipids have been implicated as autoantigen targets in chronic ITP.[35] Autoantibodies diminish or disappear when platelet levels are restored to normal.[36,37]

Factors that trigger platelet autoantibody formation in acute ITP are not well understood. Although various mechanisms by which viruses may induce autoimmune disease have been suggested, the link between the immune response initiated by infection (or vaccination) and the subsequent production of platelet autoantibodies has not been established. Proposed mechanisms include adsorption of virus to platelets, deposition of virus-containing immune complexes onto platelet membranes, or exposure of cryptic neoantigens on the platelet surface.[38] There are data to both support[39] and refute[40] the hypothesis that acute ITP is triggered by antiviral antibodies that cross-react with platelet antigens.

Some evidence suggests that T lymphocytes also play a role in the pathogenesis of ITP. Dysregulated helper T cells can promote the expansion of antiplatelet antibody–producing B-cell clones.[41] Cytotoxic T cells from some ITP patients have the capacity to destroy platelets ex vivo.[42] CD3+ T lymphocytes from ITP patients are resistant to glucocorticoid-induced apoptosis, thus suggesting that disturbed apoptosis may contribute to defective clearance of autoreactive T lymphocytes.[43]

Genetic factors have been proposed to influence the development of ITP. Studies have failed to detect linkage of the disease to particular HLA genotypes. Polymorphisms in genes encoding phagocyte Fcγ receptors or proinflammatory cytokines may influence the development of ITP.[44] Immunodeficiency states that have been associated with chronic ITP are discussed later.

Clinical and Laboratory Features. The typical manifestation of acute ITP is the abrupt onset of bruising and bleeding in an otherwise healthy child. Frequently, there is a history of a viral illness in the weeks preceding the onset of bruising. Seasonal fluctuation in the diagonsis of ITP has been noted, with a peak during spring and a nadir in the autumn.[45] Petechiae and ecchymoses are evident in most patients. Epistaxis and oral mucosal bleeding are seen in fewer than a third of patients. Hematuria, hematochezia, or melena is evident in fewer than 10%. Menorrhagia may be observed in adolescent women with ITP. Although children with ITP may have extremely low platelet counts, bleeding episodes are less severe in these patients than in those with hypoproductive thrombocytopenia. This finding has been attributed to enhanced platelet production and young, large, hemostatically effective circulating platelets.[46] A palpable spleen is present in about 10% of reported cases of childhood ITP; this finding alone should not justify performing imaging studies on the affected child's abdomen.[47] Malaise, bone pain, and adenopathy are uncommon and should raise concern for another cause, such as acute leukemia.

TABLE 34-1 Characteristics of Childhood Versus Adult Immune Thrombocytopenic Purpura

Childhood ITP	Adult ITP
Females = males	Females > males (2 : 1)
Abrupt onset	Insidious onset
Infectious prodrome common	Infectious prodrome uncommon
<20% chronic	>50% chronic

ITP, Immune thrombocytopenic purpura.

The peak age at diagnosis is 2 to 6 years. Although acute ITP may be diagnosed in children of any age, adolescents and infants are more likely to have chronic ITP develop in combination with some other immune disorder. In children ITP is seen equally in males and females, whereas in adults ITP is seen predominantly in females by a 2-to-1 ratio (Table 34-1).

Roughly 80% of children have platelet counts below 20,000/μL, often less than 10,000/μL.[24,30] Leukocyte and red cell counts are usually normal, although anemia may be seen in as many as 15% of these children, especially those with a significant history of epistaxis, hematuria, or gastrointestinal bleeding. A review of the peripheral blood film is mandatory in every child suspected of having ITP; features inconsistent with a diagnosis of ITP should prompt further investigation. Bone marrow aspiration or biopsy reveals normal or increased numbers of megakaryocytes. Increased numbers of eosinophils and their precursors may be noted, although this is not predictive of outcome.

The need for bone marrow examination in children with typical features of acute ITP is a subject of debate. There is a consensus that bone marrow aspiration is not necessary if the initial management is observation alone or administration of intravenous immunoglobulin (IVIG) or anti-D. Controversy exists regarding whether bone marrow aspiration should be performed in all children before glucocorticoid therapy is started to exclude the possibility of acute leukemia (see Box 34-2).

Additional tests that may be considered in the initial evaluation and management of suspected ITP include blood group and Coombs test (required if anti-D therapy is contemplated), quantitative immunoglobulin levels (before IVIG therapy), and antinuclear antibody test. Retrospective studies have shown that the antinuclear antibody test is positive in approximately 30% of pediatric patients with otherwise uncomplicated ITP and may predict a subset of patients at risk for the development of further autoimmune symptoms.[48] Tests not considered useful unless specific reasons are identified in the patient's history and physical examination include screening coagulation tests, liver and renal function tests, serum complement levels, thyroid function tests, and testing for human immunodeficiency virus (HIV) or *Helicobacter pylori* infection.[47]

Options for the Initial Management of Immune Thrombocytopenic Purpura. Childhood acute ITP is usually a benign, self-limited disorder that requires minimal or no therapy in the majority of cases.[24,29,49-52] There is no convincing evidence that medical therapy alters the natural history of the disease. Indications for treatment vary among practitioners and are a source of debate.[29,49,53] One set of practice guidelines put forth by the American Society of Hematology (ASH)[31] recommends that children with ITP and platelet counts less than 20,000/μL plus significant mucosal membrane bleeding or those with platelet counts less than 10,000/μL and minor purpura be treated with IVIG or a glucocorticoid. However, many pediatric hematologists take exception to this recommendation.[50,52] In treatment guidelines put forth by other expert panels, a child's condition, rather than the platelet count, steers management; children with bruising but without mucosal or more severe hemorrhage may be treated by observation alone, irrespective of the platelet count.[49,53]

At the heart of the treatment debate is the perceived risk for ICH, a rare but potentially life-threatening complication in children with ITP. In a review of 12 case series involving 1293 children, the incidence of ICH was 0.9%.[29] Other surveys[30,54-57] suggest that this may be an overestimate and that the true incidence of ICH in children with ITP is between 0.1% and 0.5%. The subgroup of children with ITP who appear to be at greatest risk for ICH are those with platelet counts less than 20,000/μL and additional risk factors such as a history of head trauma, aspirin use, or arteriovenous malformation.[29] However, the platelet count alone has never been shown to predict the severity of bleeding symptoms.[28]

There is no evidence that medical therapy, such as administration of a glucocorticoid or IVIG, reduces the incidence of ICH. Indeed, retrospective studies[56-58] have shown that ICH may occur despite previous or concomitant therapy with IVIG or a glucocorticoid. The low incidence of ICH in children with ITP precludes a randomized clinical trial to determine whether treatment reduces the risk.

The results of randomized trials for various treatment approaches have been summarized previously.[29] Regardless of whether pharmacologic therapy is used, detailed education and careful follow-up should be provided to the patient and family. The child's activities should be limited, and aspirin-containing medications should be avoided. Although hospitalization is appropriate for the treatment of a child with a severe bleeding episode, there is no evidence to support routine hospitalization of patients with otherwise uncomplicated ITP.

OBSERVATION ONLY. For a patient with ITP and only minor purpura, medical therapy may not be necessary. There is uniform consensus that patients with platelet counts greater than 20,000/μL and only minor purpura do not require therapy. As noted earlier, management of patients with platelet counts lower than 20,000/μL and minor bleeding is controversial.

FIRST-LINE MEDICAL THERAPIES. Glucocorticoids: Glucocorticoids are presumed to act through several mechanisms, including inhibition of both phagocytosis and antibody synthesis, improved platelet production, and increased microvascular endothelial stability.[59] The latter effect may explain why symptomatic bleeding episodes often subside before the platelet count increases.

In randomized trials prednisone therapy has been shown to induce normalization of the platelet count more promptly than placebo does.[60-62] Although various doses have been used, the traditional glucocorticoid regimen is prednisone at 2 mg/kg/day (maximum of 60 to 80 mg) for approximately 21 days.[60] A regimen of 4 mg/kg/day for 7 days and then tapered to day 21 is equally effective and appears to cause fewer side effects.[62] Prednisone at a dose of 4 mg/kg/day orally for 4 days with no tapering is also effective.[63] An alternative to these regimens is megadose pulse therapy (methylprednisolone, 30 mg/kg/day intravenously or orally for 3 days).[64] Side effects of glucocorticoid therapy include cushingoid facies, weight gain, fluid retention, acne, hyperglycemia, hypertension, moodiness, pseudotumor cerebri, cataracts, growth retardation, avascular necrosis, and osteoporosis.

IVIG: Imbach and colleagues[65] first reported the successful use of IVIG for the treatment of acute ITP in a small series of children. This was followed by many reports that documented the ability of IVIG to cause a rapid increase in the platelet count in patients with acute and chronic ITP.[66-68]

IVIG slows the clearance of antibody-coated blood cells from the circulation by inhibiting the phagocytic activity of cells of the reticuloendothelial system.[69] Studies in the early 1980s suggested that this effect is mediated primarily through the Fc portion of IgG. Specially treated preparations of intravenous IgG lacking the Fc portion of the molecule were inferior to unmodified IgG at increasing the platelet count in ITP patients. The proposed mechanism for this effect was Fc receptor blockade.[69] Subsequent studies of FcγRIIB-deficient mice[70] suggested that IVIG elicits its effect by activating these inhibitory receptors and not simply by Fc receptor blockade (Fig. 34-3). However, recent publications cast doubt on the conclusion that IVIG acts through activation of FcγRIIB.[71,72] Although some data support the notion that anti-idiotypic antibodies may also be present in commercial preparations and contribute to the action of IVIG,[73]

Figure 34-3 Mechanism of action of intravenous IgG (IVIG) in immune thrombocytopenia. Binding of antibody-coated platelets to activating Fcγ receptors (FcγRIII) on macrophages results in the production of phosphatidylinositol 3,4,5-triphosphate (PI[3,4,5]P$_3$) via the action of phosphatidylinositol 3′-kinase (PI3K). These activated macrophages phagocytose the platelet-antibody complexes. IVIG induces expression of the inhibitory Fc receptor (FcγRIIB) on macrophages. Stimulation of the inhibitory receptor results in recruitment of SHIP, a 5-phosphatase that degrades PI(3,4,5) P$_3$ into phosphatidylinositol 3,4-bisphosphate PI(3,4)P$_2$. *(Modified from Lin SY, Kinet JP: Immunology: giving inhibitory receptors a boost.* Science *291:446, 2001.)*

the clinical importance of this mechanism remains unproved.

The traditional dose of IVIG is 2 g/kg divided over a period of 2 to 5 days. However, several studies suggest that lower doses are effective. In a randomized trial,[67] pediatric patients who received 0.8 g/kg IVIG had at least as rapid a response rate as those who received 2 g/kg over a 2-day period. In more recent randomized trials,[68,74] favorable results have been seen with even lower doses of IVIG (250 mg/kg/day for 2 days). Among pediatric patients in whom a response is seen, IVIG produces a more rapid increase in platelet count than do traditional doses of a glucocorticoid (2 mg/kg/day of prednisone), as documented in controlled trials.[62,75]

Several other general conclusions have emerged from studies on IVIG in pediatric patients.[76] First, both splenectomized and nonsplenectomized patients may respond to IVIG. Second, responses to IVIG are generally reproducible. Third, the duration of the response is brief, approximately 2 to 4 weeks.

Enthusiasm for the use of IVIG is offset by cost considerations. IVIG is considerably more expensive than glucocorticoids or anti-D.[77] One study concluded that IVIG may be cost-effective if it reduces hospital stay or if it prevents the need for a splenectomy.[66]

Complications associated with IVIG are common and occur in 15% to 75% of patients.[29] Frequent side effects include flulike symptoms such as headache, nausea, lightheadedness, and fever. Some of these adverse effects can be alleviated by pretreatment with analgesics or antihistamines. Approximately 10% of patients treated with IVIG (2 g/kg) experience aseptic meningitis manifested as a severe, protracted headache and photophobia.[78] These symptoms, which can cause considerable anxiety in patients, parents, and physicians, may spur additional diagnostic studies (e.g., computed tomography) or result in prolonged hospitalization. A rare but serious side effect of IVIG infusion is anaphylaxis, which can occur in patients who are totally deficient in IgA.[79] Most preparations of IVIG contain small amounts of IgA, and IgE antibodies responsible for anaphylaxis form after an initial exposure to IgA in these preparations.

Anti-D: Anti-D is a plasma-derived immunoglobulin prepared from donors selected for a high titer of anti-Rh_0(D) antibody. Anti-D elicits a rise in platelet count, along with mild to moderate anemia, in most patients with ITP.[67,77,80-83] A role for anti-D in the treatment of chronic ITP is now well established. Its utility in acute ITP has been studied less extensively, but it is also effective in this clinical setting.[81,83,84]

Anti-D can be used to treat only Rh_0(D)-positive patients with ITP because Rh_0(D)-negative patients do not show a response. The presumed mechanism of action is phagocytic cell blockade. Patients with intact spleens are more likely to respond to anti-D than splenectomized patients are.

The generally recommended dose is 50 to 75 µg/kg as a short intravenous infusion[81] or subcutaneous injection.[85] Uncontrolled studies have demonstrated that anti-D treatment increases the platelet count in approximately 80% of Rh_0(D)-positive children.[80,82] The therapeutic effect of anti-D lasts for 1 to 5 weeks. A controlled trial showed that anti-D therapy was less effective than IVIG or a glucocorticoid in terms of days required to attain a platelet count of 20,000/µL.[67] Anti-D is less expensive than IVIG, with an estimated cost savings of 35% per episode of ITP.[77] The shorter administration time required for anti-D therapy also makes the medication more convenient to use than IVIG.

Adverse reactions of headache, nausea, chills, dizziness, and fever have been reported in 3% of infusions, and these adverse reactions were classified as severe in only a minority of cases.[78,86] Some degree of hemolysis, the main adverse reaction with anti-D, is inevitable because of binding of anti-D antibody to Rh_0(D)-positive erythrocytes. There is laboratory evidence of hemolysis in most patients. The average decline in hemoglobin ranges from 0.5 to 1 g/dL,[81-83] and most cases of hemolysis do not require medical intervention. In a small subset of patients, more significant hemolysis has been observed, which has tempered enthusiasm for use of the drug. Postmarketing surveillance by the U.S. Food and Drug Administration[87] documented 15 cases of hemoglobinemia or hemoglobinuria after anti-D therapy. Of these patients six required transfusion, eight experienced an onset or exacerbation of renal insufficiency, and two underwent dialysis. The incidence of intravascular hemolysis was estimated to range from 0.1% to 1.5%. Why certain patients experience severe intravascular hemolysis after anti-D therapy is unclear. Subcutaneous delivery of anti-D may be associated with a lower incidence of severe hemolytic reactions.[85]

Relapses or Treatment Failures. Many patients treated with a glucocorticoid, IVIG, or anti-D will become thrombocytopenic again after a few weeks. These patients are likely to respond again to the therapy used initially. Patients who require therapy and whose thrombocytopenia does not respond to initial treatment with a glucocorticoid, IVIG, or anti-D are usually treated with one of the alternative frontline therapies. No clinical studies document the response rate in these instances. Patients with persistent mild hemorrhage may benefit from low-dose glucocorticoid therapy.

Management of Chronic Immune Thrombocytopenic Purpura. In approximately 20% of children in whom ITP is diagnosed, thrombocytopenia persists for longer than 6 months. Chronic ITP is more common in female adolescents and adults than in their male counterparts. Chronic ITP sometimes occurs in association with other autoimmune diseases or in conjunction with an underlying condition known to predispose to disorders of autoimmunity, such as lymphoma (Box 34-3).

In up to a third of children with chronic ITP, spontaneous remission will occur months or years later. It is unclear why the condition resolves in these individuals. An estimated 5% of children with chronic ITP have recurrent ITP characterized by intermittent episodes of thrombocytopenia followed by lengthy periods of remission. This is presumed to reflect a chronic compensated state of ITP. During periods of remission, increased platelet production balances the increased rate of platelet destruction. During exacerbations, platelet production by

the marrow is suppressed by viral infections or other factors and is unable to offset the rate of destruction.

Evaluation of patients with chronic ITP should include bone marrow aspiration, if not already done; screening tests for immunodeficiency (e.g., quantitative immunoglobulin levels/subsets, specific antibody titers, lymphocyte subsets), systemic lupus erythematosus (SLE), and other autoimmune diseases (antinuclear antibody tests, direct Coombs test, antiphospholipid antibody tests, thyroid function tests); and serologic testing for HIV. Obtaining blood counts and peripheral blood smears from the parents may help exclude familial disorders.

The primary goal of treatment in patients with chronic ITP is to prevent bleeding, not cure the disease. As with acute ITP, therapy decisions should be based more on symptoms than on platelet count. In formulating a treatment plan, the physician must balance the potential side effects of treatment with the risk of bleeding episodes caused by the disease. Because the goal of treatment is a safe platelet count, not necessarily a normal platelet count, observation alone is an appropriate approach for many patients, especially those with minimal symptoms.[88]

SPLENECTOMY. Splenectomy is thought to be effective because in most patients the spleen is the major site of both platelet destruction and autoantibody production. Platelet survival studies indicate improved platelet life span after splenectomy.[57]

Splenectomy remains the most predictable intervention to achieve long-term remission in children with chronic ITP.[47] Splenectomy should be considered in a pediatric patient with chronic ITP whose risk for hemorrhage precludes the use of observation alone. However, there is debate about where splenectomy belongs in the therapeutic decision tree for chronic ITP (see Box 34-2). Because remissions are often delayed in children and the risk of postsplenectomy sepsis is significant, especially in children younger than 5 years, splenectomy is deferred longer in children with ITP than in adults. ASH practice guidelines[29,52] recommend that splenectomy be considered for children in whom ITP has persisted for at least 1 year and who have bleeding symptoms and a platelet count of less than 10,000/µL (ages 3 to 12) or 10,000 to 30,000/µL (ages 8 to 12 years). Practice guidelines in the United Kingdom are similar.[55]

Laparoscopic splenectomy is preferred over open splenectomy in children with chronic ITP.[89,90] Advantages of the laparoscopic procedure include less postoperative pain, earlier return of gastrointestinal function, shorter hospitalization, more rapid resumption of normal activities, and smaller incisions. To ensure adequate hemostasis, the platelet count can be raised preoperatively with a glucocorticoid, IVIG, or anti-D. Despite these interventions, many patients will still have thrombocytopenia at the time of splenectomy; however, most will not exhibit excess bleeding. Accordingly, prophylactic platelet transfusions are not warranted. Instead, platelet transfusions should be reserved for patients with intraoperative bleeding. Most experienced surgeons have become comfortable performing laparoscopic splenectomy on patients with platelet counts in the range of 50,000 to 100,000/µL. Overall perioperative mortality is less than 1%.

The majority of children with chronic ITP respond to splenectomy. In a review[29] of 16 case series involving 271 children undergoing elective splenectomy for chronic ITP, a complete remission rate of 72% was reported. The platelet count usually rises immediately after splenectomy and reaches a maximum 1 to 2 weeks postoperatively. If the peak platelet count achieved after splenectomy is greater than 500,000/µL, permanent remission is likely.[91] Certain patient characteristics are associated with a higher probability of response to splenectomy, including a previous response to glucocorticoid therapy.[92-94] However, there is no single factor or combination of factors that will predict the response to splenectomy in all cases.[95]

Relapse after an immediate response to splenectomy may result from transient viral suppression of thrombopoiesis. If the thrombocytopenia persists, an accessory spleen should be considered. Approximately 40% of patients with persistent thrombocytopenia will have a residual accessory spleen that can be seen with sensitive imaging techniques such as ^{99m}Tc sulfur colloid scans (Fig. 34-4) or ^{111}In platelet localization studies.[96] Many of these patients will achieve complete remission after removal of the accessory spleen.[96] The presence of Howell-Jolly bodies on a peripheral blood smear does not rule out an accessory spleen.

The major risk after splenectomy is fatal sepsis caused by encapsulated organisms. The risk of septicemia in splenectomized patients is estimated to be 1 per 300 to 1000 patient-years.[97] To lessen the risk of future sepsis, patients should receive vaccinations for pneumococcus, *Haemophilus influenzae* type b, and meningococcus at least 2 weeks before surgery.[98] In addition, penicillin prophylaxis is indicated for splenectomized patients younger than 5 years. The benefit of penicillin prophylaxis in older asplenic children is controversial.[99]

PHAGOCYTE BLOCKADE. Intermittent maintenance therapy with a glucocorticoid, IVIG, or anti-D can be used to delay splenectomy. These medications may also be useful in the management of patients with chronic ITP who experience symptomatic thrombocytopenia after splenectomy.

In some patients a safe platelet count can be maintained with low doses of prednisone. However, even low doses of prednisone, comparable to physiologic cortisol secretion, can cause osteoporosis.[100]

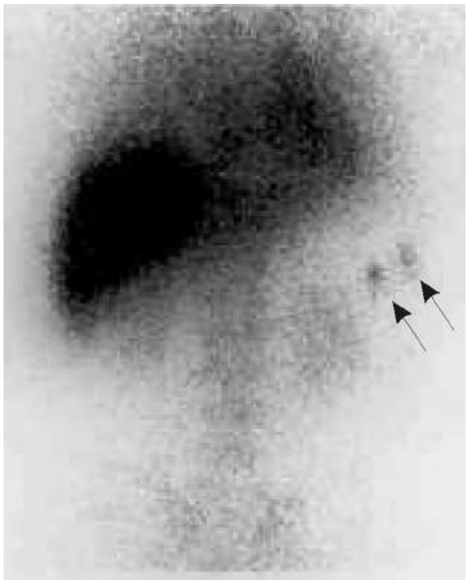

Figure 34-4 Detection of accessory spleens after splenectomy. A sulfur colloid scan shows accessory spleens *(arrows)* in a teenage girl with chronic immune thrombocytopenic purpura and persistent thrombocytopenia after splenectomy. *(Courtesy Dr. Robert Minkes, Louisiana State University.)*

IVIG (1 to 2 g/kg total dose administered) elevates the platelet count in most children with chronic ITP.[61,62] Periodic doses of IVIG may be used as maintenance therapy to defer splenectomy in young children with chronic ITP.[66] This approach is cost-effective in young children.[101] In approximately 25% of children, ITP will become refractory to maintenance therapy with IVIG.[102] Low-dose alternate-day prednisone therapy can be used as an adjunct to maintenance IVIG therapy. Although repeated infusions of IVIG induce short-term platelet responses in most patients with chronic ITP, there is no evidence that such therapy will affect the natural history of the disease and induce a long-lasting remission.

Anti-D administration raises the platelet count in most Rh_0(D)-positive children with chronic ITP. However, the benefit is usually transient, with a median duration of 3 to 5 weeks.[103] Anti-D can be effective as maintenance therapy in patients who are not appropriate candidates for splenectomy or other therapies because of young age or other factors.[103,104] In Rh_0(D)-positive patients with chronic ITP, anti-D is preferred over IVIG because of ease of administration, comparable efficacy, and lower cost.

MONOCLONAL ANTIBODIES THAT TARGET B CELLS OR T CELLS. Rituximab: Rituximab, a humanized monoclonal antibody directed against CD20, is now commonly used to treat chronic ITP despite limited clinical trial data documenting its efficacy in children with this condition (see Box 34-2).[105] Rituximab is generally administered in four weekly intravenous infusions of 375 mg/m^2 each, but there is no standard dose for rituximab in children.[106] There are reports of children with ITP who responded to lower doses of rituximab.[106] This agent causes rapid depletion of pre-B cells and B cells that lasts for 6 to 12 months. Pre-B cells efficiently present antigen to T cells, and disruption of this interaction may attenuate the autoimmune response. Approximately 30% to 60% of patients with chronic ITP respond to rituximab.[107-113] The initial response may be immediate (within 1 week) or delayed (up to 3 months).[107-113] Relapses are common but often respond to retreatment. The estimated 5-year sustained response rate in children is 26%.[113] Side effects of rituximab include fever, urticaria, pruritus, throat tightness, and serum sickness.[110] Another serious complication associated with rituximab is progressive multifocal leukoencephalopathy (PML).[112] More than 50 cases of PML have been reported in patients treated with rituximab, including a patient with ITP.[114]

Alemtuzumab: Alemtuzumab (Campath 1H) is a humanized monoclonal antibody that targets CD52, a protein on both B and T cells. There are anecdotal reports of its use in patients with chronic ITP.[115] Part of the effect of alemtuzumab can be attributed to B-cell depletion, analogous to rituximab, and part to depletion of T cells. Unlike rituximab, alemtuzumab induces profound generalized immunosuppression associated with opportunistic infections.[105]

OTHER IMMUNOSUPPRESSIVE AGENTS. A large number of other immunosuppressive medications have been used to treat refractory ITP, as reviewed elsewhere.[48,116,117] No randomized studies have evaluated the effectiveness of these various therapies. The choice of therapy must be individualized to the patient.

Azathioprine: Azathioprine acts preferentially on lymphocytes and was one of the first drugs reported to be effective in the treatment of chronic refractory ITP.[118,119] Recommended doses range from 50 to 200 mg/m^2/day orally. Continuous therapy for 4 to 6 months is required before a patient is considered unresponsive. Once a response is obtained, the dose should be tapered to the lowest level that results in a hemostatic platelet count. In adults with refractory ITP treated with azathioprine, approximately 20% achieve a complete response and 45% exhibit a partial response. Relapse often occurs when the therapy is stopped. The combination of azathioprine and oral steroids may be synergistic, and azathioprine therapy may allow a reduction in the dose of glucocorticoids. Toxicities include dose-related leukopenia, opportunistic infection, and an increased risk for malignancy.

Cyclophosphamide: The alkylating agent cyclophosphamide has also been used to treat chronic refractory ITP, with a response rate similar to that with azathioprine.[119] Greater risks are associated with the use of cyclophosphamide than with azathioprine. Side effects include myelosuppression, alopecia, nausea, infertility, teratogenicity, hemorrhagic cystitis, and an increased risk for malignancy.

Cyclosporine: The potent immunosuppressive agent cyclosporine disrupts T-cell function through calcineurin inhibition. There are case reports of patients with refractory ITP who had increases in platelet counts after treatment with cyclosporine.[120] Response rates vary. A starting dose of 5 mg/kg/day given in divided oral doses is recommended, with the aim of maintaining a serum cyclosporine level of 200 to 400 ng/mL. The drug should be discontinued after 4 weeks if there is no response. Hypertension, renal insufficiency, hirsutism, and liver dysfunction are common side effects.

Tacrolimus: Though not structurally related to cyclosporine, tacrolimus has a similar mechanism of action and has been used anectodally to treat chronic ITP.[41] Initial dosing recommendations for tacrolimus in children are 0.15 to 0.3 mg/kg/day given in divided oral doses. Doses should be adjusted to maintain trough tacrolimus concentrations of 5 to 20 ng/mL in whole blood. Common adverse effects associated with tacrolimus include hypertension, tremor, headache, and hyperglycemia.

Mycophenolate mofetil: There are reports showing the effectiveness of another immunomodulatory drug, mycophenolate mofetil (MMF), in patients with steroid-resistant chronic ITP.[121,122] MMF is a prodrug of mycophenolic acid, a noncompetitive inhibitor of inosine-5α-monophosphate dehydrogenase, a key enzyme in the purine biosynthetic pathway. MMF inhibits proliferation of both T cells and B cells. In one series[122] a sustained platelet increase to a level greater than 50,000/μL was seen in 7 of 18 patients with refractory ITP. For adults the usual starting dose is 250 mg orally twice daily, with an increase to 1 g twice daily by 3 weeks. MMF has few side effects and is generally well tolerated.

Vinca alkaloids: The vinca alkaloids vincristine and vinblastine may induce a response in some patients with chronic refractory ITP.[123] These drugs bind tubulin and inhibit microtubule polymerization, which is presumed to disrupt phagocytosis. Either vincristine or vinblastine may be used; the efficacy of the two drugs is comparable. The usual dose of vincristine is 1.5 mg/m^2 (maximum of 2 mg) intravenously, whereas the dose of vinblastine is 6 mg/m^2 (maximum of 10 mg) intravenously. These doses are repeated weekly for a month. If no response is seen, additional doses are unwarranted because subsequent improvement is unlikely. Patients who show a response often require repeated doses at 2- to 3-week intervals to maintain a safe platelet count. In adults the response rate is approximately 12%, and the partial response rate is 35%. The response rate in children is not established and varies considerably in the reports available. Adverse effects include peripheral neuropathy, constipation, and alopecia. Vinblastine causes dose-related myelosuppression.

Danazol: Danazol, an attenuated androgen with mild virilizing effects, has been shown to increase the platelet count in patients with refractory ITP, although the mechanism of action is uncertain. Approximately 40% of adult patients respond to danazol with an increase in platelet count to greater than 50,000/μL.[124] A typical dose is 300 to 400 mg/m^2/day orally, although smaller doses (50 mg/m^2) have been reported to be effective.[125] In general, 2 months of therapy is required before a response is seen. Often the medication must be continued to maintain the platelet count, although effort should be made to minimize the dose. Danazol may be especially useful for the treatment of older adolescent or adult women with chronic, refractory ITP and uncontrollable menorrhagia. Side effects of danazol include acne, fluid retention, hirsutism, deepening of the voice in women, headache, nausea, rash, breast tenderness, and oligomenorrhea or amenorrhea. Patients should be monitored for the development of liver toxicity.

Interferon alfa: Although the mechanism is unknown, 25% of adults with chronic ITP treated with interferon alfa display a significant, albeit transient, increase in platelet count.[126] Interferon-alfa has also been used to treat children with chronic ITP.[127] The recommended dose is 3 million U/m^2 subcutaneously three times per week for 4 weeks. Adverse effects of interferon alfa include flulike symptoms and neutropenia.

Combination chemotherapy: Combination chemotherapy with or without autologous stem cell transplantation has been used successfully to treat some adults with chronic, refractory ITP, with an overall sustained remission rate of approximately 40%.[128,129]

THROMBOPOIESIS-STIMULATING AGENTS. In ITP the rate of platelet production is inadequate to offset the increased rate of platelet destruction.[31] Two newer drugs for the treatment of chronic ITP act by stimulating thrombopoiesis. Romiplostim is a recombinant protein that contains two domains: a peptide that binds to the thrombopoietin (TPO) receptor c-Mpl and an antibody Fc domain that increases the half-life in circulation.[130] In a placebo-controlled, phase II study this agent was efficacious when administered subcutaneously on a weekly basis (1 to 3 μg/kg) to adults with chronic ITP.[131] Toxicity was minimal. In children there has been one randomized clinical trial of romiplostim[132] and several case series.[106,133,134] Romiplostim increased the platelet count in 88% of the children in this study, and quality-of-life measurements documented reduced parental burden.[135] Another small-molecule c-Mpl agonist for chronic ITP is eltrombopag,[130] which binds to the transmembrane region of c-Mpl rather than the TPO binding site. This agent is given orally once daily. A phase II trial on adults with chronic ITP showed that eltrombopag at doses of 50 and 75 mg was significantly better than placebo at increasing platelet counts to greater than 50,000/μL. The drug appears to have few side effects, one of which is reversible liver toxicity.[136] Romiplostim and eltrombopag are licensed for use in adults with chronic, severe ITP but not yet for use in children.

One concern is that myelofibrosis may develop after prolonged treatment with TPO receptor agonists.[106] A slight but significant increase in reticulin fibrosis has been demonstrated in the bone marrow of adult patients receiving TPO receptor agonists.[137] Until additional safety data are collected, monitoring for marrow changes with an annual bone marrow biopsy seems prudent. Thromboembolic events have also been reported in patients treated with romiplostim and eltrombopag.[106] Other limitations for the use of TPO receptor agonists include cost, the indefinite duration of therapy required, and the risk of severe thrombocytopenia in patients who interrupt therapy.[106,138]

Management of Life-Threatening Hemorrhage in Immune Thrombocytopenic Purpura. ICH or another life-threatening form of bleeding mandates intervention with multiple therapeutic modalities, including IVIG (1 g/kg), anti-D (50 to 75 μg/kg), high-dose glucocorticoids (e.g., methylprednisolone, 30 mg/kg intravenously), platelet transfusions, or a combination of these interventions. Because IVIG and anti-D act to inhibit phagocytosis by distinct and potentially synergistic mechanisms (see Fig. 34-3), these two agents may be used together for instances of severe bleeding. TPO receptor agonists have a limited role in this setting because it takes an average of 2 weeks to see a response.[106] Recombinant factor VIIa has also been used in the management of ICH in patients with thrombocytopenia refractory to platelet-enhancing agents.[139] If a craniotomy is required, consideration should be given to splenic artery embolization[140] or emergency splenectomy,[141] although most hematologists reserve splenectomy for patients in whom ITP does not respond rapidly to therapy with glucocorticoids, IVIG, anti-D, and platelet transfusions.[29,142] Optimal therapy for ICH also includes supportive care with mechanical ventilation and mannitol.

Thrombocytopenia Associated with Lymphoproliferative and Autoimmune Disorders. Chronic ITP may be a manifestation of an associated autoimmune disease or immunodeficiency state. This is especially true in young children in whom chronic, refractory ITP develops or in adolescent girls with systemic symptoms.

Autoimmune lymphoproliferative syndrome (ALPS) is a rare syndrome that occurs in early childhood and is characterized by massive, nonmalignant lymphadenopathy, splenomegaly, hypergammaglobulinemia, and autoimmune manifestations, including immune thrombocytopenia and hemolytic anemia (see Chapter 13).[143] ALPS has been linked to inherited defects in *FAS* and other genes that regulate lymphocyte apoptosis. An abnormal accumulation of lymphocytes results in lymphadenopathy, hepatosplenomegaly, and hypersplenism. In young children the lymphadenopathy may be pronounced and then wane later in life. Impaired elimination of autoreactive lymphocytes also causes autoimmune manifestations, including autoantibody formation. Patients with ALPS commonly exhibit episodic autoimmune cytopenia, including thrombocytopenia, hemolytic anemia, neutropenia, or combined cytopenias.

A significant proportion of young children with chronic ITP may have a variant of ALPS.[144-146] For example, in one survey[145] of 20 pediatric patients with chronic cytopenia, 25% were found to have profound defects in Fas-mediated lymphocyte death. Two of these patients, ages 4 and 9 years, had chronic refractory ITP without other clinical manifestations of ALPS. Neither patient had an identifiable mutation in *FAS* or caspase-10, and it is presumed that they may have defects in one of the molecules involved in Fas signaling. Similar results have been reported in other studies,[144,146] thus suggesting that altered Fas signaling, independent of *FAS* mutations, is associated with and may precipitate chronic hematologic autoimmunity, including ITP.

The lymphadenopathy and cytopenias associated with ALPS generally respond to glucocorticoid therapy. Mycophenolate mofetil and sirolimus are also highly effective in the treatment of ALPS.[147] Because rituximab may lead to prolonged hypogammaglobulinemia when used in ALPS, alternative immunosuppressants should be tried before using this agent.[147] Patients with ALPS have a very high risk of postsplenectomy sepsis, so splenectomy is not recommended.[147]

Thrombocytopenia occurs at some time in approximately 25% of patients with SLE and may be the first manifestation of autoimmunity.[148] Both autoantibodies and complement-fixing immune complexes have been implicated in the pathogenesis of thrombocytopenia in SLE.[149] In addition, antiphospholipid antibodies are frequently observed in the sera of patients with SLE.[150] Antibodies against antigens nonspecifically adsorbed to the surface of platelets, such as DNA, have also been reported.[151]

The initial therapy for thrombocytopenia in patients with SLE is administration of a glucocorticoid, but there is a high incidence of recurrent thrombocytopenia when the steroid dose is tapered. Long-term use of low doses of glucocorticoids may be justified, especially if these drugs also control the other symptoms of SLE. Splenectomy can be used in the management of patients with SLE and chronic, symptomatic thrombocytopenia. In some case series[152] splenectomy for SLE has been shown to yield response rates comparable to those for ITP, whereas in other series[153] the response rate has been lower.

Thrombocytopenia may be associated with an antiphospholipid antibody syndrome, whether the syndrome occurs as a primary disorder or in association with SLE or another autoimmune disorder. Patients with antiphospholipid antibody syndrome often experience recurrent venous or arterial thrombotic complications rather than bleeding (see Chapter 35). Autoantibodies against GPIIb/IIIa, GPIa/IIa, and GPIb/IX have been documented in this syndrome.[154] Enhancement of platelet activation by antiphospholipid antibodies may contribute to the prothrombotic state in these patients.[155] In general, the degree of thrombocytopenia is moderate. A variety of therapies have been used to treat antiphospholipid antibody syndrome and the accompanying thrombocytopenia, including glucocorticoids and other immunosuppressive agents.

Evans syndrome is the coexistence of autoimmune hemolytic anemia and thrombocytopenia. Autoimmune neutropenia also develops in many of these patients (see Chapter 13).[156] Frequently, patients with Evans syndrome have associated disorders, such as dysgammaglobulinemia. Distinct antiplatelet and antierythrocyte antibodies rather than cross-reactive antibodies are responsible for the association of autoimmune hemolytic anemia and thrombocytopenia. In many patients the course of the disorder is marked by exacerbations of thrombocytopenia, anemia, or neutropenia. Unlike the majority of patients with ITP or isolated autoimmune hemolytic anemia, therapy with glucocorticoids, IVIG, or splenectomy often fails in patients with Evans syndrome.[156] Patients with Evans syndrome have been treated with rituximab, which induces remission in the majority, although relapses tend to occur within 12 months.[156] Other options for treatment include mycophenolate mofetil and cyclosporine.[156] For severe and refractory cases, hematopoietic stem cell transplantation is a consideration.

Immune thrombocytopenia can complicate other autoimmune diseases, including dermatomyositis, juvenile rheumatoid arthritis, Hashimoto thyroiditis, Graves disease, myasthenia gravis, inflammatory bowel disease, sarcoidosis, and protein-losing enteropathy.[157-160] Immune thrombocytopenia can also precede, accompany, or follow neoplastic disease, especially lymphoproliferative disorders such as Hodgkin and non-Hodgkin lymphoma.[161] Immune thrombocytopenia has also been seen in association with childhood acute lymphoblastic leukemia.[162] In some patients the thrombocytopenia of neoplastic disease resolves in response to antineoplastic therapy, whereas in others the thrombocytopenia requires specific treatment.

Thrombocytopenia occurs in 5% to 10% of patients with HIV infection. Immune-mediated platelet destruction is a major contributor to the thrombocytopenia seen in patients with HIV. The antibodies in HIV-associated thrombocytopenia are directed against the same target epitopes commonly seen in idiopathic ITP—namely, epitopes on GPIIb/IIIa.[163] Immune complexes composed of anti-idiotype antibodies and antibodies directed against the HIV antigen gp160/120 may also induce platelet destruction.[163] Whereas half of patients with ITP have normal or increased platelet production, most patients with HIV-associated thrombocytopenia have decreased platelet production.[164] Infection of megakaryocytes or bone marrow stromal cells may account for the reduced platelet production noted in HIV-associated thrombocytopenia.

Thrombocytopenia may occur early in the course of HIV infection and is often seen within the first 2 years.[165] Platelet counts are rarely lower than 50,000/μL, and symptomatic bleeding is uncommon. However, in HIV-infected patients with hemophilia, the bleeding can be more severe, even life threatening. Therapy is similar to that for ITP, except that HIV-associated thrombocytopenia may respond to antiviral therapy. Patients with severe or symptomatic thrombocytopenia that persists despite antiviral therapy should be managed in the same way as patients with severe ITP.

Neonatal Alloimmune Thrombocytopenia. NAIT, also termed fetomaternal alloimmune thrombocytopenia, is a syndrome characterized by transient, isolated, severe thrombocytopenia. The syndrome results from placental transfer of maternal alloantibodies directed against paternally inherited antigens present on fetal platelets but absent from maternal platelets. Therefore this condition is the platelet counterpart of hemolytic disease of the newborn.

Alloantigens. Platelet alloantigens and the platelet membrane glycoproteins on which they reside are listed in Table 34-2. Most of the antigens were originally named on the basis of the patient's surname. In many cases duplicate names were assigned to the same alloantigens (e.g., Pl^{A1} = Zw^{a}, Pen^{a} = Yuk^{b}). The HPA, or human platelet antigen, nomenclature was proposed in the 1990s to systemize platelet alloantigens.[166-168] Each HPA system represents a biallelic polymorphism caused by a single amino acid substitution (see Table 33-2).

In white populations the most frequently implicated alloantigen in NAIT is HPA-1a (Pl^{A1}), which accounts for 78% of serologically confirmed cases.[169] Incompatibility for the HPA-5b alloantigen is the next most common cause. Approximately 98% of white individuals express the HPA-1a antigen on their platelets; most of the remaining 2% are homozygous for an alternative allele that encodes the HPA-1b (Pl^{A2}) antigen. The protein products of these two alleles differ only by a single amino acid (Leu33 versus Pro33). The incidence of NAIT is approximately 1 in 2000 births,[170] which is much lower than the predicted incidence based on distribution of the HPA-1a and HPA-1b alleles in the population. Other immune

response genes appear to regulate HPA-1a alloantibody formation. Women with the HLA-DR3 antigen have about a twentyfold relative risk of forming HPA-1a alloantibodies. In Asian populations incompatibility of the HPA-4 system is the most common cause of NAIT (80%), followed by incompatibility of the HPA-3 system.[171] HLA class I antigens are expressed on platelets, and maternal sensitization to HLA has been implicated as a cause of NAIT in a few patients.[172] HLA alloantibodies are present in 10% to 30% of pregnant women, especially multiparous women. The relative rarity of NAIT secondary to HLA alloantibodies may result from binding of these antibodies to the placenta or other tissues. Blood group ABH alloantibodies have been found in a small number of patients with NAIT.[173]

Clinical and Laboratory Features. The degree of thrombocytopenia in NAIT can be severe, with platelet counts of less than 10,000/μL on the first day of life.[173] Common hemorrhagic manifestations include petechiae (90%), hematomas (66%), and gastrointestinal bleeding (30%). The maternal platelet count is normal, an important laboratory value for distinguishing this condition from neonatal thrombocytopenia secondary to maternal ITP[174] (discussed later). Unlike Rh disease of the newborn, NAIT can occur in both the first and subsequent pregnancies. A history of a previously affected infant provides strong supportive evidence for a diagnosis of NAIT.

Patients with NAIT are at increased risk for ICH, both prenatally and postnatally.[170,173] About 15% of affected neonates have ICH, and 50% of these cases occur antenatally. In utero bleeding can result in hydrocephalus, porencephaly, seizures, or fetal loss.[175] The pronounced bleeding diathesis associated with anti–HPA-1a alloimmune thrombocytopenia may reflect the combination of severe thrombocytopenia and antibody-mediated interference with the function of the GPIIb/IIIa complex on the few remaining platelets.

Treatment. The diagnosis of NAIT is confirmed by serologic or genotypic testing, including immunophenotyping of maternal, paternal, and occasionally neonatal platelets; maternal or fetal serum also can be examined for the presence of antiplatelet antibody. Several sensitive assays have been developed for platelet antigen typing and detection of alloantibody.[176] Despite the availability of sensitive tests, serologic evidence of alloantibodies is lacking in a least a third of cases identified by clinical criteria; therefore NAIT is a clinical diagnosis. Because delays may be associated with serologic testing, therapy should be initiated as soon as the diagnosis is suspected.

The treatment of choice for severe NAIT (platelet count <30,000/μL or clinically significant bleeding) is transfusion of washed, irradiated maternal platelets (Fig. 34-5).[168] Irradiation prevents transfusion-associated graft-versus-host disease. In the interest of time, normal donor screening procedures may have to be abridged. There are often medical or practical reasons that maternal platelets cannot be collected in a timely manner. Random-donor platelet infusions can be used in the treatment of NAIT if maternal platelets are not immediately available.[177] However, only a modest and short-lived increase in the platelet count may be observed after the infusion of random-donor platelets. IVIG (1 g/kg daily for 2 days) or a glucocorticoid (methylprednisolone, 2 mg/kg/day) can also be used as a temporary measure, although these interventions may be of limited benefit. If the offending alloantigen is known, platelets from an antigen-negative unrelated donor may be used. In white populations the use of HPA-1a– and HPA-5b–negative donors has been advocated because these two antigens are responsible for more than 95% of cases of NAIT. To provide transfusion support for fetuses and neonates with NAIT, the National Blood Service of England has established an accredited platelet donor panel of HPA-1a–negative individuals with no antibodies to HLA, HPA, or red cell antigens.[178] The majority of these donors are HPA-5b negative.

Platelets produced by neonates with alloimmune thrombocytopenia may exhibit accelerated clearance for weeks, until antiplatelet antibody is removed from the circulation (see Fig. 34-5). Consequently, it is not unusual for additional transfusions of maternal (or an antigen-compatible unrelated donor) platelets to be required after the first few weeks of life.

Management of Future Pregnancies. The likelihood is high that subsequent infants born to mothers of infants with NAIT will be affected. Moreover, the severity of antenatal and postnatal hemorrhage tends to increase in later pregnancies.[179] Therefore detailed counseling on the risk of recurrence should be provided to the family at the time that thrombocytopenia is diagnosed in the first infant. Although the neonate's thrombocytopenia may have resolved before completion of the full diagnostic laboratory evaluation, it is important that the diagnosis and presumed antigen incompatibility be confirmed by formal serologic and genotypic testing to guide the management of future pregnancies. Antibody titers begin to decline after delivery; thus the evaluation should ideally be initiated in the postpartum period. Because the likelihood of thrombocytopenia in subsequent infants depends on whether the father is HPA-1a homozygous or HPA-1a/1b heterozygous, performance of DNA-based genotyping is desirable.

Fetuses at risk for ICH should be monitored with serial ultrasound examinations, although fetal ICH may not always be detected by this method. In some centers prenatal diagnosis of the platelet alloantigen genotype has been performed with DNA obtained by chorionic villus sampling or amniocentesis. More commonly, percutaneous umbilical blood sampling is performed at 20 to 22 weeks of gestation to obtain a fetal platelet count and perform platelet antigen typing. However, this procedure may be associated with fetal loss because of exsanguination; thus compatible antigen-negative (e.g., maternal) platelets should be available when percutaneous umbilical blood sampling is performed and should be infused if the fetus is severely thrombocytopenic.[170]

When the diagnosis of alloimmune thrombocytopenia is confirmed in the fetus, two antenatal treatment approaches are available. In most North American centers, the favored approach is weekly maternal infusion of IVIG.[180,181] In some European centers the preferred approach for severe cases of alloimmune thrombocytopenia is repeated in utero platelet transfusions; administration of IVIG and a glucocorticoid is reserved for mildly affected fetuses.[181]

Neonatal Autoimmune Thrombocytopenia. This condition can occur in infants of mothers with immune thrombocytopenia as a result of ITP, SLE, or other autoimmune disorders and is caused by placental transfer of maternal autoantibodies.[174] Antigens implicated as causes of neonatal autoimmune thrombocytopenia mirror those seen in ITP. In general, this condition is less serious than NAIT.

This diagnosis should be considered when both the neonate and the mother exhibit signs of thrombocytopenia or in infants of mothers with a previous history of immune thrombocytopenia. Neonatal thrombocytopenia has been observed in infants of mothers rendered asymptomatic for chronic ITP by splenectomy. Maternal ITP must be distinguished from the mild decrease in platelets that frequently accompanies pregnancy at term, presumably because of plasma volume expansion.[182]

The thrombocytopenia associated with maternal immune thrombocytopenia is generally milder than NAIT. The incidence of cord platelet counts lower than 50,000/μL is only about 3%,[183] and the incidence of ICH is only about 1%.[174] Although clinically significant bleeding episodes are rare, newborns with this condition should be monitored closely because platelet counts often decrease in the days after birth. The threshold for medical intervention in neonates with thrombocytopenia differs from that in older children with ITP because of concern about ICH in the newborn. A platelet count of less than 40,000 to 50,000/μL in a neonate is considered by many to be a useful indicator for starting therapy. IVIG (1 g/kg daily for 2 days) elevates the platelet count in most patients.[184] A glucocorticoid (methylprednisolone, 2 mg/kg/day) may be used in addition to or in lieu of IVIG therapy.

Perinatal management of mothers with immune thrombocytopenia, including the mode of delivery of a thrombocytopenic fetus, is controversial. Because the cord platelet count rarely is below 50,000/μL, perinatal ICH is uncommon and not necessarily related to delivery. The degree of maternal thrombocytopenia is a poor predictor of the degree of neonatal thrombocytopenia, although the clinical course of thrombocytopenia in the first sibling does predict that of the next sibling.[174] Otherwise, there are no reliable predictors of severe thrombocytopenia in the newborn. Direct determination of the fetal platelet count by percutaneous umbilical venous sampling can be performed, but this procedure is rarely justified for this condition.

Posttransfusion Purpura. PTP is a very rare syndrome in childhood. Typically, this syndrome affects a multiparious woman with HPA-1a–negative platelets who is reimmunized with that alloantigen through blood transfusion.[185] Severe, acute thrombocytopenia ensues 1 week later, presumably reflecting an anamnestic response to the platelet alloantigen. PTP has been reported to develop in males and in nulligravida females as a result of initial exposure to the alloantigen through a previous blood transfusion. HPA-1a is the alloantigen found in 90% of occurrences of PTP.

Alloantibodies cause PTP, but the mechanism of platelet destruction is unclear. Several hypotheses[185] have been put forward to explain how alloantibody promotes destruction of autologous platelets, including immune complex–mediated platelet destruction; adsorption of allogeneic platelet antigens onto autologous platelets, which renders them susceptible to alloimmune destruction; and transient induction of autoantibodies. Because on average 2% of transfusion recipients have an HPA-1a incompatibility and PTP is very rare, other factors probably influence the development of this syndrome. Thrombocytopenia is usually severe (platelet count <10,000/μL), and hemorrhage is common. A high-titer alloantibody is often detectable. Patients generally recover in a few weeks. However, life-threatening bleeding, including

ICH, may occur. Prednisone and plasma exchange have been used, but IVIG is probably the treatment of choice for severe occurrences.[186] Random-donor platelet infusions are ineffective and should not be administered. The efficacy of compatible, alloantigen-negative platelet transfusions is controversial.

Severe, transient thrombocytopenia has been associated with passive transfusion of plasma-containing products that have high-titer alloantibodies against HPA-1a or HPA-5b.[187] This condition has been reported in neonates.[188] The thrombocytopenia occurs within hours of transfusion. Most patients recover spontaneously, but treatment with IVIG or a glucocorticoid should be considered for severely affected patients.[188]

Drug-Induced Immune Thrombocyopenia. Numerous drugs have been implicated as causes of antibody-mediated thrombocytopenia.[189,190,191] In general, the risk associated with any drug is low, but some drugs cause immune thrombocytopenia more commonly than others do. The thrombocytopenia generally resolves when use of the drug is discontinued, but the severity of bleeding symptoms and the duration of thrombocytopenia vary widely among patients. In some instances the sensitizing drug induces a second, drug-independent antibody (autoantibody) in addition to a drug-dependent one.[192] Usually, these drug-induced autoantibodies are transient and disappear when treatment with the drug is discontinued. Occasionally, however, autoantibody production may be sustained and lead to a clinical picture indistinguishable from that of ITP.[192] Once established, sensitivity to a drug generally persists indefinitely.[189]

Pathogenesis. Several mechanisms have been implicated in drug-induced immune thrombocytopenia.[189]

HAPTEN FORMATION. Small compounds can become covalently linked to blood cell membrane proteins and stimulate the production of antibodies specific for the hapten-protein complex. This mechanism is responsible for the hemolytic anemia seen in some patients treated with penicillin (see Chapter 13). Similarly, antibodies directed against hapten-protein complexes appear to be responsible for cases of penicillin-induced thrombocytopenia.[193]

COMPOUND EPITOPE FORMATION. In patients with quinine-induced thrombocytopenia, antibodies that bind to normal platelets can be detected only when quinine is present in the soluble phase. These antibodies are usually specific for GPIIb/IIIa[194,195] or GPIb/IX.[196] The mechanism by which quinine promotes binding of antibody to platelets is not well understood. It is postulated that this agent binds noncovalently to one or more platelet membrane proteins and creates a “compound epitope” recognized by an antibody. Alternatively, the drug may interact with the target protein and cause a conformational change elsewhere in the molecule for which the antibody is specific.[197] In addition to quinine, sulfonamide antibiotics and certain other drugs have been shown to induce antibodies that bind to platelets only when the sensitizing drug or one of its metabolites is present in the soluble state.[189] Among children sulfamethoxazole is one of the more common causes of drug-induced immune thrombocytopenia.

DRUG-INDUCED AUTOANTIBODIES. Certain drugs, such as gold salts, procainamide, levodopa, and interferon alfa, induce true autoantibodies that bind to platelet membrane targets in the absence of the drug.[189,198] The mechanisms by which these drugs induce autoantibodies is poorly understood.[192]

Clinical Features. Severe thrombocytopenia generally develops within 1 day of ingestion of quinine in a previously sensitized individual. A minimum of 1 week is required for initiation of the primary immune response in individuals taking this drug for the first time. Prodromal symptoms such as fever and chills may be observed. Bleeding may be severe, and its onset is abrupt. Hemorrhagic vesicles are common in the oral mucosa. The presence of a platelet antibody may be verified by a variety of techniques. Readministration of a suspected drug in an attempt to confirm an etiologic relationship is not recommended as a routine diagnostic measure.

Treatment. Discontinuation of treatment with the offending drug is the main therapy. With quinine the thrombocytopenia usually begins to abate in 1 day if no additional drug is taken, and a normal platelet count is restored within 1 week. In patients with severe drug-induced thrombocytopenia, IVIG or a glucocorticoid has been used to ameliorate bleeding.[199] However, there is little evidence that these medications are effective in this clinical setting. For life-threatening hemorrhage, platelet transfusion may be used, although this may be of limited value because of the persistence of slowly dissociating drug-antibody complexes. Because a sensitized individual is presumed to remain at lifelong risk for additional episodes of drug-induced thrombocytopenia, further use of the offending drug is contraindicated.

Heparin-Induced Thrombocytopenia and Thrombosis. HIT is a complex clinical syndrome with an overall estimated incidence of 1% to 5% in adult patients exposed to heparin; the incidence in children is probably less, and it is virtually nonexistent in neonates.[200-202] The thrombocytopenia usually begins 5 to 10 days after heparin therapy is started, but it can occur within hours if the patient previously received heparin.[201] The risk of HIT is higher for therapeutic than for low drug doses, for bovine than for porcine heparin, and for unfractionated than for low-molecular-weight heparin (LMWH).[203] In contrast to drug-induced thrombocytopenia caused by quinine or sulfonamides, severe thrombocytopenia (platelet count <10,000/μL) is rare in HIT. Typically, platelet counts range from 20,000 to 150,000/μL, with a median of 50,000/μL.[189,204] The thrombocytopenia itself is rarely severe enough to cause bleeding symptoms and resolves after heparin therapy is discontinued. However, as many as 30% of patients with HIT experience arterial or venous thromboses. The development of thrombosis in patients with HIT is known as thrombocytopenia with thrombosis syndrome (HITTS), and this condition is associated with significant morbidity and mortality.

Pathogenesis. The antibodies responsible for HIT recognize the complex of heparin and platelet factor 4 (PF4), an alpha granule constituent.[205] After treatment with heparin, PF4 is released into the circulation and binds with heparin to form a reactive antigen on the platelet surface.[204] The heparin-PF4 complex is immunogenic in some patients. IgG against this complex triggers platelet activation by binding to FcγRIIA receptors on the surface membrane. The activated platelets release substances that stimulate other platelets and result in thrombin generation.[206] PF4 bound to glycosaminoglycans on the surface of endothelial cells may also serve as a target for antibody binding and lead to antibody-mediated injury to the endothelium and a predisposition to thrombosis.[207]

Approximately 50% of patients exposed to heparin during cardiac catheterization and subsequently during cardiac surgery form antibodies against heparin-PF4 complexes, but HITTS develops in only a small percentage.[208] It is unclear why heparin-PF4 complexes, which are composed of two substances normally present in the body, are so immunogenic. Moreover, it is not known why thrombocytopenia or thrombosis develops in some patients and not in others.

Diagnosis. The diagnosis of HIT is based on the interpretation of clinical findings together with laboratory confirmation of heparin-PF4 antibodies. A scoring system has been proposed to assess the pretest probability of HIT,[209] although this system has not been validated for pediatric patients. The gold standard laboratory test for diagnosing HIT is a functional test, the platelet [^{14}C] serotonin release assay. Unfortunately, the complexity and availability of this assay limit its usefulness. An enzyme-linked immunosorbent assay (ELISA) for detection of antibodies against heparin-PF4 complexes is available, and results obtained with the serotonin release assay and ELISA are generally in agreement in patients with a clinical diagnosis of HIT.[203,210] However, ELISA has a more limited specificity and therefore produces false-positive results. A negative ELISA result generally excludes HIT. If the ELISA result is positive, a serotonin release assay may be performed to confirm the diagnosis or to invalidate a false-positive ELISA result.[211]

Treatment. It is standard practice to discontinue heparin in patients in whom HIT is suspected, but many of these patients will have thrombotic complications over the subsequent days. Therefore ongoing antithrombotic therapy is indicated. Patients with HIT should not be given warfarin as a substitute for heparin during the acute episode because this can cause an abrupt decrease in the level of protein C and put the patient at greater risk for thromboembolic complications such as warfarin-induced limb gangrene.[196,212] LMWH is not recommended for the treatment of HIT because unfractionated heparin and LMWH preparations display significant platelet aggregation cross-reactivity in vitro and in vivo.[203,213] Hirudin, a compound originally purified from the leech salivary gland, inactivates thrombin by forming a 1:1 complex. A recombinant hirudin, lepirudin, is effective in the treatment of HIT or HITTS.[214] In children lepirudin should be started as a continuous infusion at 0.1 mg/kg/h without a preceding bolus, with a target activated partial thromboplastin time (APTT) of 1.5 to 2.5 times the patient's baseline value (first assessed 4 hours after infusion).[200] Other agents that are effective in this clinical setting are the synthetic antithrombin argatroban[215] and the synthetic pentasaccharide fondaparinux.[216] Danaparoid, a low-molecular-weight heparinoid consisting of a mixture of heparan sulfate, dermatan sulfate, and small amounts of chondroitin sulfate, has been used for more than a decade to treat patients with HIT.[217] Danaparoid was voluntarily withdrawn from the United States market with the introduction of fondaparinux but is still available in other countries.

Thrombotic Microangiopathic Disorders. The thrombotic microangiopathic spectrum of disorders is characterized by destructive thrombocytopenia, disseminated capillary thrombosis, and microangiopathic hemolytic anemia (Box 34-4). Often organ dysfunction occurs because of microvascular thrombosis and ischemic necrosis. Thrombotic microangiopathic disorders may be primary or secondary. There are both acute and chronic (familial) relapsing forms.

The two major thrombotic microangiopathic disorders affecting children and adolescents are thrombotic thrombocytopenic purpura (TTP), a classic disease of hematology, and hemolytic-uremic syndrome (HUS), a classic disease of nephrology. Patients with TTP always have thrombocytopenia and schistiocytic hemolysis, frequently with central nervous system and renal impairment. In HUS the microangiopathic process is usually but not always limited to the kidneys. However, the boundary between these two clinical syndromes may be nebulous. Renal impairment can be prominent in TTP, and neurologic injury can occur in HUS. In adults these two microangiopathic syndromes are often viewed as a joint entity termed *TTP-HUS*.[218] In pediatrics, however, the two syndromes are generally considered to be distinct, albeit overlapping, entities. In addition to TTP and HUS, other conditions can produce schistiocytic hemolysis and thrombocytopenia, including bone marrow transplant–associated microangiopathy (see Box 34-4).

Thrombotic Thrombocytopenic Purpura. TTP is a syndrome characterized by reversible aggregation of platelets in the microvasculature that results in waxing and waning ischemia in various organs.[219-221] The defining clinical features of TTP are listed in Table 34-3. The pentad of thrombocytopenia, microangiopathic

hemolytic anemia, neurologic abnormalities, fever, and renal abnormalities is present in many patients. Before the development of an effective therapy, the risk of mortality associated with the disease was greater than 90%. With the advent of plasma infusion/exchange therapy, TTP has become a curable disease. There are two major forms of TTP: an acute, acquired form and a rare, inherited, chronic relapsing form. Acute TTP can be further subcategorized into primary (idiopathic) and secondary forms. Drugs, infections, and other factors have been associated with secondary TTP.

PATHOPHYSIOLOGY. The characteristic pathologic lesion of TTP is a hyaline thrombus composed of aggregated platelets in the absence of a perivascular inflammatory response. The thrombotic lesions of TTP typically involve terminal arterioles and capillaries and are most commonly seen in the brain, abdominal viscera, and heart, but not the lungs. Red blood cells are damaged as a result of interactions with microthrombi in the small vessels.

Immunohistochemistry of early lesions of TTP reveals an abundance of von Willebrand factor (VWF) but little fibrin.[222,223] VWF within these thrombi is thought to be critical in pathogenesis. In 1982 unusually large multimers of VWF (UL-VWF) were observed in the plasma of patients with chronic relapsing TTP (Fig. 34-6).[224,225] UL-VWF multimers are most prominent in plasma samples taken from these patients during remission and decrease at the time of relapse. These UL-VWF multimers, which are synthesized by endothelial cells, are composed of increased numbers of mature VWF subunits. Under conditions of shear stress, the UL-VWF forms are more efficient than other VWF multimers at binding to the GPIb/IX/V and GPIIb/IIIa complexes on platelets and inducing aggregation.[224,226,227] These findings, coupled with the observation that VWF was abundant in the early thrombotic lesions of TTP, led to the hypothesis that intravascular platelet aggregation in TTP was due to either excessive release of UL-VWF multimers into plasma or impaired degradation of these UL-VWF multimers into smaller, nonaggregating forms.

Under ordinary circumstances, UL-VWF multimers are processed into multimers of normal size through the action of ADAMTS13, a VWF-cleaving metalloproteinease in normal plasma.[228,229] This protease cleaves a specific Tyr-Met bond in the second of the three A domains in VWF subunits (Fig. 34-7).[230] Physiologically, UL-VWF multimers are thought to be cleaved by ADAMTS13 under conditions of high shear stress, which partially unfolds the molecules. In vitro this partial denaturation can be mimicked by guanidinium or urea treatment.

Acquired or constitutional deficiency of the VWF-cleaving protease predisposes individuals to TTP. Chronic relapsing TTP, which usually begins in early childhood, is caused by loss-of-function mutations in the ADAMTS13 gene.[231-234,235] The acute TTP more commonly seen in adults is usually caused by an acquired deficiency in

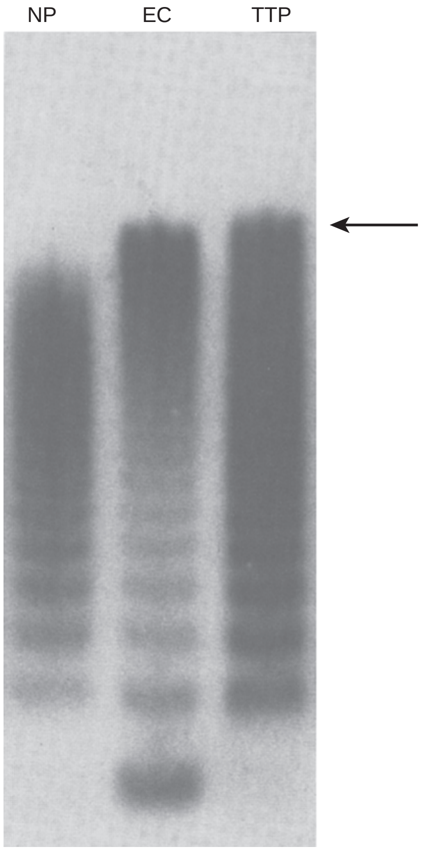

Figure 34-6 Autoradiogram demonstrating unusually large multimers of von Willebrand factor (VWF) near the top of the gel *(arrow)* in the plasma of a patient (thrombotic thrombocytopenic purpura [TTP]) obtained early during a single episode of TTP. Normal pooled plasma *(NP)* and the culture supernatant from human umbilical vein endothelial cells *(EC)* are shown for comparison. EDTA-anticoagulated samples were subjected to agarose gel electrophoresis in sodium dodecyl sulfate–urea-EDTA. VWF multimers were visualized by incubation with ^{125}I-labeled rabbit antihuman VWF antibody followed by autoradiography. *(From Moake JL, Chow TW: Thrombotic thrombocytopenic purpura: understanding a disease no longer rare.* Am J Med Sci *316:108, 1998.)*

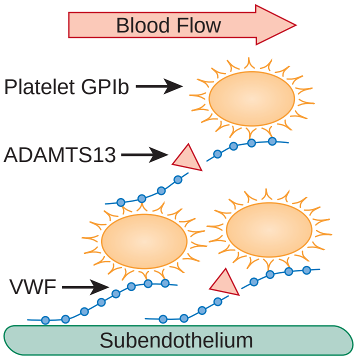

Figure 34-7 Pathogenesis of thrombotic thrombocytopenic purpura (TTP). The von Willebrand factor (VWF) multimers facilitate platelet adhesion to the subendothelium by binding to exposed connective tissue and then to platelet glycoprotein Ib (GPIb). In flowing blood shear stress unfolds ultralarge VWF multimers in the platelet-rich thrombus and enables ADAMTS13 to cleave a specific Tyr-Met bond in the second of the three A domains in VWF subunits. Cleavage reduces VWF multimer size and limits thrombus growth. In the absence of ADAMTS13, VWF-dependent platelet accumulation continues and eventually results in microvascular thrombosis and TTP. *(Courtesy Dr. Evan Sadler, Washington University.)*

VWF-cleaving protease activity resulting from an IgG autoantibody against ADAMTS13.[236,237] The reasons for this transient immune dysregulation and for the selective antigenic targeting of ADAMTS13 are unknown. Fresh frozen plasma, cryoprecipitate-poor plasma (cryosupernatant), and plasma treated with solvent or detergent all contain the VWF-cleaving protease activity, which presumably accounts for the efficacy of plasma exchange therapy (discussed later).

CLINICAL FEATURES. TTP is a relatively rare disorder with an estimated annual incidence of 1 to 4 per million population.[238,239] TTP is more common in women than in men (ratio of 3:2) and has a peak incidence in persons between the ages of 30 and 40 years. The condition has been reported in adolescents; indeed, the first instance reported in the literature was a teenage female.[220] The incidence of the disease is increasing, in part because of increased awareness of the condition and the availability of effective therapy.[218,240]

TTP usually develops in previously healthy individuals (idiopathic TTP). In approximately 15% of patients, the syndrome is associated with an underlying condition (secondary TTP), such as bacterial or viral infection,[241,242] pregnancy,[243] collagen vascular disorders,[244] pancreatitis,[245] and malignancy.[246] Several drugs[230] have been associated with the development of secondary TTP, including ticlopidine, clopidogrel, lopidogrel, quinine, mitomycin C, cyclosporine, and tacrolimus. The mechanisms by which these drugs promote TTP are not well understood. Inhibitory antibodies against ADAMTS13 have been observed in ticlopidine- and clopidogrel-associated TTP.[247,248]

In the usual occurrence of TTP, the onset of symptoms is abrupt. The most common initial manifestations are bleeding and neurologic abnormalities. The neurologic symptoms can progress rapidly and may include headache, confusion, stupor, coma, hemiparesis, cranial nerve palsies, and seizures. Fever is uncommon initially but invariably develops during the course of the disease. TTP is a clinical diagnosis that rests on the signs and symptoms presented in Table 34-3. The primary diagnostic criteria are thrombocytopenia and microangiopathic hemolytic anemia. Some patients may not be anemic initially, although their hematocrit levels may fall sharply afterward, and in some patients red cell fragmentation may not be apparent.[249] Therefore the diagnosis of TTP initially is often provisional. Serum lactate dehydrogenase (LDH) levels are increased, frequently to very high levels, because of not only hemolysis but also diffuse tissue ischemia. If considerable tissue ischemia and necrosis are present, disseminated intravascular coagulation (DIC) may ensue.

The diagnosis of TTP can be confirmed by measuring ADAMTS13 activity and by screening for inhibitory antibodies against this enzyme.[235] These tests may also provide prognostic information in cases of idopathic TTP. In one prospective study[250] 6 of 14 patients (43%) with severe ADAMTS13 deficiency later relapsed, whereas only 2 of 25 patients (8%) without severe ADAMTS13 deficiency relapsed. In two other series[251,252] patients with detectable anti-ADAMTS13 antibodies had a higher mortality rate than patients without detectable antibodies did. More recently, the presence of high-titer anti-ADAMTS13 IgA has been associated with a higher mortality rate.[253]

Though less common than acquired TTP secondary to autoantibodies, TTP caused by mutations in the ADAMTS13 gene is an autosomal recessive disease (also referred to as Upshaw-Schulman syndrome) that can be manifested at birth or in early childhood, with rare patients remaining asymptomatic until adulthood. The age at onset and severity can be highly variable, even among patients in the same family (carrying the same ADAMTS13 mutation).[230-235] Congenital TTP occurring in early childhood may be misdiagnosed as chronic ITP or Evans syndrome.[235]

TREATMENT. Congenital TTP typically exhibits a chronic relapsing course that usually requires long-term treatment with fresh frozen plasma to replace the deficient ADAMTS13 protein. The regimen is determined empirically, and stable remission can generally be maintained with plasma infusions as infrequently as once every few weeks to months.[224,225,231-233]

Plasma exchange is the mainstay of therapy for acquired TTP (secondary to anti-ADAMTS13 autoantibodies). At least 50% to 80% of patients recover with this therapy. A randomized trial demonstrated the superiority of plasma exchange over plasma infusion.[254] This finding has been attributed to removal of antibody against VWF-cleaving protease. Another randomized study showed that fresh frozen plasma and cryoprecipitate-poor plasma were equally effective in the initial treatment of adults with TTP.[255] The risks of plasma exchange are substantial and include hemorrhage and catheter-related complications such as pneumothorax and infection.[246] Glucocorticoid therapy is often used as an adjunct to plasma exchange therapy, but there is no direct evidence that the addition of glucocorticoids produces results that are superior to those of plasma therapy alone.[218]

Although TTP in most patients responds to plasma exchange therapy, the response is varied. Mental status changes may resolve immediately. Typically, the initial recovery from thrombocytopenia requires several days. Serum LDH levels may improve promptly, but patients often remain dependent on red cell transfusion for days. Recovery from renal failure is generally slow. Chronic renal insufficiency, defined as creatinine clearance of less than 40 mL/min/1.73 m^2 at 1 year after diagnosis, occurs in about 25% of patients.

Preliminary studies[256-258] suggest that rituximab can induce a complete response in patients with idiopathic TPP who are refractory to plasma exchange. This agent may also be beneficial as prophylatic therapy in patients with idiopathic TTP who are at high risk for relapse.[256-258]

Patients with secondary TTP caused by dose-related drug toxicity (e.g., mitomycin C) or allogeneic marrow transplantation may not benefit from plasma exchange treatment. Likewise, the course in a patient who has a clinically apparent additional condition, such as SLE, is unpredictable. Management of plasma exchange treatment is often dictated by the activity of the associated condition.

Hemolytic-Uremic Syndrome. HUS is another microangiopathic hemolytic anemia characterized by capillary thrombosis and ischemic necrosis. The kidneys are the end organs most severely affected, but ischemic injury of the intestines, central nervous system, or other organs may occur. HUS typically follows a diarrheal illness (mainly *Escherichia coli* O157:H7 infection) but also occurs in nonenteropathic settings. HUS occurs most often in infants and young children and is the most common cause of acute renal failure in this age group. The annual incidence is approximately 1 in 100,000 and may be increasing.[259] HUS can also occur in adults, particularly in the elderly, which suggests that susceptibility to HUS is greatest at the extremes of age.

ENTEROPATHIC HEMOLYTIC-UREMIC SYNDROME. Pathogenesis: Certain strains of enteric bacteria produce a toxin that is cytopathic to Vero cells, a monkey kidney cell line. In the early 1980s Karmali and associates[260] reported that 75% of children with HUS had evidence of gastrointestinal infection by verotoxin-producing *E. coli*. Subsequent studies showed that strains of other enteric pathogens, including *Shigella, Salmonella,* and *Campylobacter,* produce verotoxin and can cause HUS.

The term *verotoxin* has been replaced by the term *Shiga toxin* or *Shigalike toxin* (Stx). This toxin is the key factor that differentiates infection with enterohemorrhagic *E. coli* (EHEC), which is associated with watery diarrhea, hemorrhagic colitis, and HUS, from enteropathogenic *E. coli* (EPEC), which is associated only with watery diarrhea and vomiting. Stx1 and Stx2, the two most prevalent forms of the toxin found in EHEC strains, are encoded by bacteriophages. Stx1 is identical to Shiga toxin produced by *Shigella dysenteriae* type I. Stx2 is immunologically distinct from Stx1.[261]

Stx is structurally related to ricin and cholera toxin. Each of these toxins is composed of a single A subunit noncovalently associated with a pentamer of identical B subunits.[261] The enzymatic activity of the toxin resides in the A subunit, whereas the B subunits are required for cellular uptake. Stx is taken up via endocytosis and transported to the endoplasmic reticulum via retrograde trafficking through the secretory pathway.[262] The A subunit enters the cytosol and targets 28S ribosomal RNA, which is depurinated by the toxin at a specific adenine residue and causes protein synthesis to cease and the infected cells to die by apoptosis. Renal microvascular endothelial cells appear to be particularly sensitive to Stx.[263,264] Hemorrhagic enterocolitis has been ascribed to the action of Stx on endothelial cells in vessels of the intestinal submucosa. The toxin also inhibits protein synthesis in certain nonendothelial cells, including renal mesangial and cortical tubular cells.[265,266] Because EHEC is not invasive, it has long been assumed that HUS-related tissue damage results from the spread of bacterial products from the intestine to the kidney and other target organs. It is thought that Stx enters the systemic circulation after translocation across the intestinal epithelium.[267]

Clinical and laboratory features: Approximately 50% of cases of acquired HUS appear after gastrointestinal infection with *E. coli* O157:H7. For unclear reasons, HUS develops in only 9% to 30% of persons with *E. coli* O157:H7 colitis. Elevated leukocyte counts and C-reactive protein levels have been identified as risk factors for progression to HUS.[268,269] Other risk factors are the extremes of age, the presence of bloody diarrhea, and the use of antimotility drugs.[270]

Gastrointestinal symptoms can range from mild to severe. The colonic mucosa is hemorrhagic and edematous; ischemic infarcts can occur in the colon, and perforations have been reported. Stool cultures may be positive for the pathogenic organism.[271] Other diagnostic techniques include demonstration of Stx or specific bacterial DNA in stool samples or a rise in the titer of specific antibodies.

The anemia and thrombocytopenia associated with HUS tend to be less severe than those associated with TTP. The platelet count is greater than 100,000/μL in half of the patients, and bleeding is uncommon. Laboratory evidence of DIC is not usually present, but it can occur, especially in HUS associated with *Shigella*. The serum LDH level is less elevated than in TTP. A study of 16 children in whom HUS developed after *E. coli* O157:H7 infection showed normal levels of VWF-cleaving protease activity in plasma.[270] This finding has been confirmed by other investigators.[272]

Acute renal failure with oliguria, hypertension, and proteinuria usually develops in affected patients. Renal histopathologic examination reveals a preglomerular and glomerular thrombotic microangiopathy.[273] Mental status changes attributable to uremia are common. More rarely, focal neurologic signs are evident.

Treatment: Supportive care is the mainstay of therapy. Parenteral volume expansion with isotonic fluid during acute *E. coli* O157:H7 enteritis may attenuate the renal injury.[274-275] Dialysis and renal transplantation are performed when necessary. Independent trials have shown that antimotility agents increase the risk for HUS after *E. coli* O157:H7 infection.[253]

There is no compelling evidence that antibiotics are beneficial in the treatment of HUS, and there is some indirect evidence that the use of antimicrobials may be dangerous. Antibiotics increase the amount of Stx released from EHEC in vitro, so antibiotic therapy might paradoxically increase the risk for HUS in vivo. A prospective controlled study[276] evaluated the effect of trimethoprim-sulfamethoxazole in children with *E. coli* O157:H7 enteritis. There was no statistically significant effect of treatment on progression of symptoms, fecal pathogen excretion, or the incidence of HUS. A prospective study of 71 children with diarrhea caused by *E. coli* O157:H7 suggested that antibiotic therapy was associated with an increased risk for HUS.[269] It is now generally accepted that antibiotics should not be administered in an effort to decrease the severity or duration of gastrointestinal symptoms or to prevent HUS in patients with *E. coli* O157:H7 enteritis.[277] There might be a role for azithromycin in elimination of Stx-producing *E. coli* from postsymptomatic carriers,[278] although this remains controversial.[277]

Other treatments that have been tried without obvious benefit include infusion of fresh frozen plasma, glucocorticoids, heparin, thrombolytic agents, and prostacyclin.[279,280] Although plasma infusion or exchange has no proven role in the management of diarrhea-associated HUS in children, this therapy may be beneficial in adults with HUS or children with nonenteropathic HUS (discussed later).[202] Despite treatment, approximately 5% of children with HUS die of the disease and 10% have severe, chronic renal impairment.[281,282]

ATYPICAL HEMOLYTIC-UREMIC SYNDROME. Approximately 10% of pediatric patients seen with an HUS-like illness do not have antecedent bloody diarrhea and are classified as having atypical HUS (aHUS). There are both familial and sporadic forms of aHUS. The associated mortality rate is higher than that of enteropathic HUS. About half of survivors have a relapse, and a third require chronic dialysis.[283]

Pathogenesis: Deficiency of complement regulators is a major risk factor for the development of aHUS. More than 50% of patients with aHUS have a mutation in one of three complement control proteins: factor H (fH), membrane cofactor protein (MCP; CD46), or factor I (fI).[284-286] Additionally, autoantibodies against fI have been described in patients with sporadic aHUS.[285] MCP and fH serve as cofactors for fI, a serine protease that inactivates C3b (and C4b) through limited proteolytic cleavage (Fig. 34-8). Deficiency of fH, MCP, or fI results in excessive complement deposition, which promotes the development of microthrombi in the kidneys and other tissues.[287]

Invasive infection with certain strains of pneumococcus can also cause aHUS.[288] These strains produce neuraminidase, which exposes the normally hidden Thomsen-Freidenreich antigen on erythrocytes, platelets, and renal glomerular cells. Naturally occuring IgM antibodies in human plasma bind the exposed antigen; promote complement fixation; and trigger anemia, thrombocytopenia, and uremia.[288] Other nondiarrheal infections have also been linked to aHUS.[289]

Treatment: Although plasma therapy is often used in the management of aHUS secondary to complement

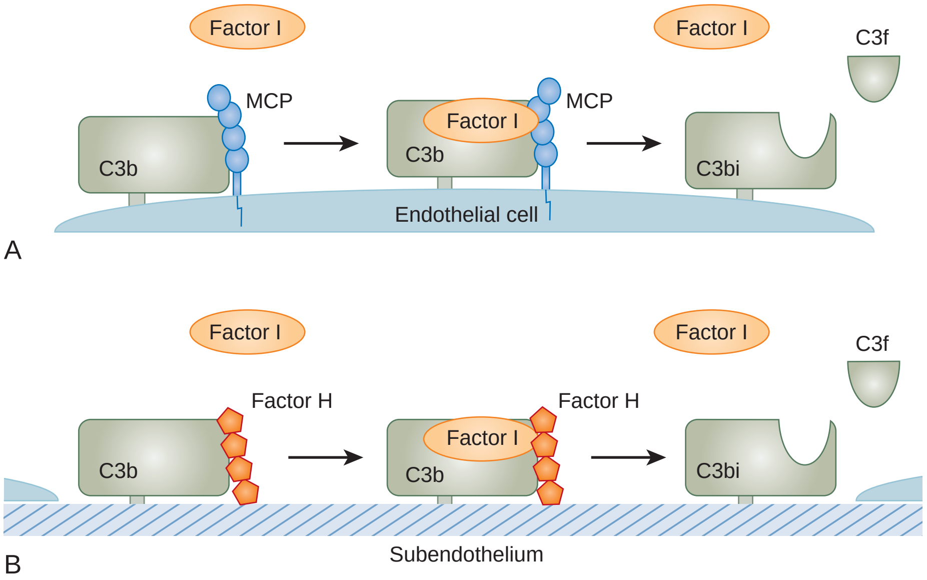

Figure 34-8 Role of complement regulatory proteins in the pathogenesis of atypical hemolytic-uremic syndrome. **A,** Membrane cofactor protein (MCP), a complement regulatory protein, is expressed on the surface of endothelial cells and other cell types and binds to C3b that has been deposited on the cell surface either spontaneously or in response to injury. In cooperation with MCP, the plasma serine protease factor I then cleaves C3b into its inactive form C3bi, thereby preventing further complement activation via the alternative pathway. In patients with MCP or factor I deficiency, excessive complement deposition occurs and leads to further cellular injury, endothelial cell necrosis, and ultimately thrombosis. **B,** Endothelial cell necrosis exposes basement membranes that are devoid of complement regulators. Factor H, a plasma-derived complement regulatory protein, binds to exposed basement membranes and, in cooperation with factor I, inactivates C3b that is deposited at these sites. Factor H deficiency leads to excess complement deposition on basement membranes. *(Courtesy Dr. J. P. Atkinson, Washington University.)*

regulator deficiency, its benefit in preventing progression to end-stage renal disease or relapse is questionable.[290-292] Patients with an MCP mutation have a satisfactory outcome after renal transplantation because MCP is a transmembrane protein and the allografts are protected by wild-type MCP.[284] In contrast, recurrent aHUS develops in patients with a deficiency of fH or fI after renal transplantation because the allograft cannot compensate for deficiency of these plasma proteins, which are produced primarily in the liver. Liver transplantation is an option for some of these patients.[286] Eculizumab, a humanized monoclonal antibody that inhibits cleavage of C5, preventing the generation of the proinflammatory peptide C5a and the membrane attack complex C5b-9, is licensed for treatment of aHUS, particularly for patients nonresponsive to plasma therapy.[287,293]

Patients with aHUS caused by neuraminidase-producing pneumococcus should receive only washed red blood cells or platelets if transfusion is required.[288] Plasma products are not recommended for use in these patients.

Bone Marrow Transplant–Associated Thrombotic Microangiopathy. Thrombotic microangiopathy has emerged as one of the major complications of bone marrow transplantation (BMT).[294] The incidence ranges from 6% to 21%.[295] It is seen after allogeneic and less commonly after autologous BMT. The diagnosis may be difficult to make because of the presence of coexisting complications of BMT, such as graft-versus-host disease, cytomegalovirus infection, and hepatic veno-occlusive disease. Although BMT-associated microangiopathy (BMT-MA) shares features with other microangiopathies such as TTP and HUS, it has a distinctive clinical course and response to therapy. The pathogenesis of BMT-MA is unknown but appears to be distinct from that of primary TTP.

The condition ranges in severity from self-limited microangiopathic hemolytic anemia to a fulminant, usually fatal disorder. The fulminant form of the disease is more common in adults than children. In one adult series[296] the incidence of BMT-MA was 2% with matched sibling donor transplants and 6% with unrelated donor transplants. Risk factors for the development of BMT-MA in adults include the use of unrelated or mismatched donors, grade II through IV acute graft-versus-host disease, and systemic bacterial or fungal infection.[295] In contrast to primary TTP, plasma exchange therapy appears to be of limited benefit in BMT-MA.[295] Most pediatric patients primarily exhibit signs of renal insufficiency. The mainstay of management is supportive care and, if feasible, a reduction of the dose of cyclosporine or tacrolimus. If the patient's clinical condition deteriorates (e.g., worsening hemolysis, progressive renal insufficiency, neurologic symptoms), plasma exchange should be considered.[294]

Other Causes of Increased Platelet Destruction. Systemic bacterial or fungal infections are also commonly associated with thrombocytopenia. The degree of thrombocytopenia may range from moderate to severe. Thrombocytopenia associated with systemic bacterial or fungal infection is usually caused by increased platelet destruction. A variety of mechanisms contribute to this destruction, including immune-mediated factors, direct effects of bacterial toxins, DIC, and hypersplenism.

Acute viral infections in children are commonly complicated by thrombocytopenia. For example, thrombocytopenia develops in about 75% of patients with infectious mononucleosis caused by Epstein-Barr virus.[297] Viral-induced thrombocytopenia may be immediate or delayed, and the decrease in platelet count may range from mild to severe. Thrombocytopenia can follow immunization with live virus vaccines. Viruses may cause thrombocytopenia through both nonimmune and immune mechanisms, including cytotoxic effects on megakaryocytes, direct injury to platelets, immune complex–mediated destruction (see earlier discussion of ITP and HIV), and hyperspenism. Thrombocytopenia is a manifestation of hemophagocytic lymphohistiocytosis. Thrombocytopenia caused by increased platelet destruction is a uniformly seen complication of malaria and African trypanosomiasis.[298]

Thrombocytopenia commonly accompanies extracorporeal membranous oxygenation, cardiopulmonary bypass, hemodialysis, and apheresis.[299] There are many causes, including adherence of platelets to synthetic materials in the perfusion device, hemodilution, hemorrhage, and drug effects (e.g., heparin). The thrombocytopenia associated with hemodialysis or apheresis is generally mild, but more severe thrombocytopenia may be seen in association with extracorporeal membranous oxygenation.

A healthy fetus has a platelet count of greater than 150,000/μL by the second trimester of pregnancy, and only 2% of term infants are thrombocytopenic at birth.[300] Severe thrombocytopenia, defined as a platelet count lower than 50,000/μL, is evident in fewer than 3 of 1000 term infants, the most important cause being NAIT. In contrast, thrombocytopenia is common among patients in neonatal intensive care units. Thrombocytopenia is also common in patients with intrauterine growth retardation and has been ascribed to placental insufficiency or chronic hypoxia. Thrombocytopenia is seen in preterm neonates with respiratory distress syndrome. Neonatal viral infections, including rubella, herpes, cytomegalovirus, and enterovirus, have also been associated with thrombocytopenia. Acute thrombocytopenia commonly accompanies necrotizing enterocolitis and is often an early sign of the disease. Thrombocytopenia is commonly seen in neonates with polycythemia, especially if they have associated cyanotic heart disease, although this phenomenon is probably multifactorial.[301] Infants with severe Rh hemolytic disease of the newborn may exhibit thrombocytopenia along with neutropenia.[302]

Kasabach-Merritt Syndrome. Kasabach-Merritt syndrome is the association between thrombocytopenia and a giant hemangioma of infancy. Most patients are seen in the first few weeks of life, although rare occurrences have been described in later childhood.[303] The vascular lesions are usually solitary and involve the extremities, neck, or trunk (Fig. 34-9). Sometimes the lesions are located in the viscera, including the retroperitoneum. The possibility of an occult hemangioma should be considered in a neonate

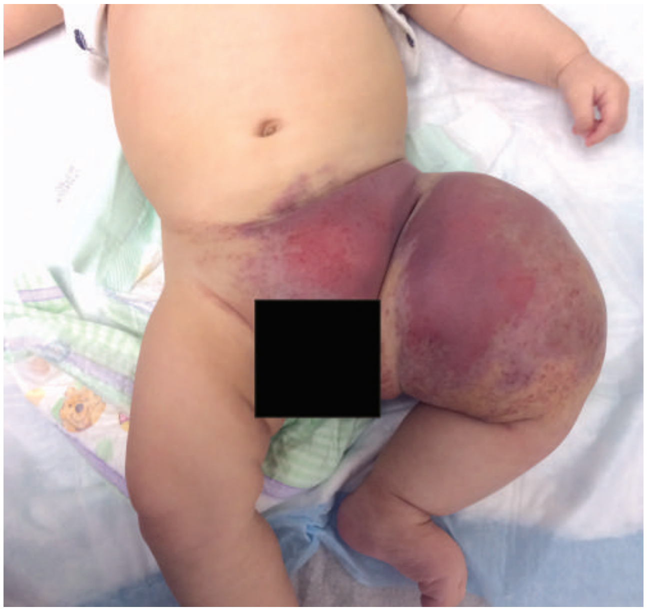

Figure 34-9 Infant with Kasabach-Merritt syndrome. Histopathology showed a kaposiform hemangioendothelioma. *(Courtesy Dr. Adam Vogel, Washington University.)*

with unexplained thrombocytopenia. Detection may require radiographic imaging of the brain, liver, spleen, or gastrointestinal tract.

The hemangiomas associated with Kasabach-Merritt syndrome have a natural history of rapid growth for several months, followed by spontaneous regression. The thrombocytopenia subsides as the hemangioma regresses. Kasabach-Merritt syndrome, which is marked by severe thrombocytopenia and spontaneous regression in the first few years of life, is distinct from the mild, chronic thrombocytopenia associated with venous malformations, which are lifelong lesions (Box 34-5).

The pathogenesis is poorly understood, but platelets are thought to be trapped by abnormal endothelium within the hemangioma. Usually, the platelet count is less than 50,000/μL, and schistocytes are frequently present on the peripheral blood film. In a majority of cases there is laboratory evidence of DIC. These tumors grow rapidly to a large size and are often characterized by cutaneous purpura, edema, and an advancing ecchymotic margin. Imaging studies are essential in delineating the extent of the lesion and determining whether it is surgically resectable. In contrast to common hemangiomas, magnetic resonance imaging shows diffuse enhancement with ill-defined margins, cutaneous thickening, stranding of subcutaneous fat, hemosiderin deposits, and small feeding and draining vessels.[303]

The mortality rate is as high as 40%,[308] and the development of a life-threatening consumptive coagulopathy warrants aggressive treatment. Surgical removal may be effective, but most lesions cannot be resected. Radiation therapy can be effective but carries serious long-term risks for a young infant[309] and is not appropriate for most patients. Vascular ligation or embolization has been used to promote regression of a large hemangioma, especially in patients in whom a solitary, major feeding vessel can be obliterated.[303] Glucocorticoid therapy may be beneficial in some patients.[303] Interferon alfa has been shown to be effective if no response to glucocorticoid therapy is seen.[310] Vincristine is another treatment option in the management of patients with Kasabach-Merritt syndrome; response rates of greater than 80% have been reported with vincristine, although complete resolution is rare and the use of vincritistine is limited by neurotoxicity and other side effects.[311,312] Propranolol, an agent highly effective at treating common infantile hemangiomas, appears to beneficial in only a minority of patients with Kasabach-Merritt syndrome.[312]

Thrombocytopenia Caused by Decreased Platelet Production

The second major etiologic classification of acquired thrombocytopenia of childhood is impaired platelet production, with the associated conditions listed in Box 34-1. Patients with thrombocytopenia caused by a production defect are more likely to have serious bleeding than patients with destructive thrombocytopenia are.

A common cause of thrombocytopenia in patients with cancer is chemotherapy-induced bone marrow suppression. This is an expected complication of therapy and rarely poses a diagnostic problem. Traditional management is straightforward and relies on transfusion of platelet concentrates and adjustment of chemotherapy doses. A recent clinical trial demonstrated that bleeding risks are higher for children versus adults given prophylactic platelet transfusions for treatment-induced hypoproliferative thrombocytopenia.[313]

Valproic acid is commonly used in the treatment of childhood epilepsy, bipolar disorder, and other conditions. Hematologic toxicity, including thrombocytopenia, is often seen in patients treated with valproate.[291] Valproate causes direct bone marrow suppression that may vary in onset and severity and is more common in patients with serum valproate levels greater than 100 μg/mL.[314] In addition to bone marrow suppression, valproate may have other effects on platelets, including immune-mediated destruction and impaired function.[314]

Box 34-5 Clinical Pearls

Hemangiomas and Kasabach-Merritt syndrome. Thrombocytopenia is evident in only a small proportion of infants with hemangiomas (0.3%).[303,304] Kasabach-Merritt syndrome is not associated with the common infantile capillary/cavernous hemangioma, which is seen in 5% to 10% of children. Rather, Kasabach-Merritt syndrome appears to be a complication of two rare, aggressive histopathologic subtypes: kaposiform hemangioendothelioma and tufted hemangioma.[305-307] The histologic features of kaposiform hemangioendothelioma and tufted hemangioma are abnormal when compared with the relatively well-organized vessels evident in capillary hemangiomas. These abnormal histologic features may contribute to platelet trapping and activation.

Thrombocytopenia can result from replacement of normal marrow elements by abnormal cells, as seen in leukemia, solid tumors (neuroblastoma, rhabdomyosarcoma, Ewing sarcoma), storage diseases, and disseminated Langerhans cell histiocytosis. Other acquired disorders of hematopoietic cells that are associated with thrombocytopenia include myelodysplastic syndrome, aplastic anemia, paroxysmal nocturnal hemoglobinuria, and osteopetrosis. In osteopetrosis the bone marrow space is obliterated by new bone formation. This condition can be diagnosed by x-ray studies but may not be clinically obvious in a neonate with thrombocytopenia. Peripheral smear findings include teardrop cells and nucleated erythrocytes.

Although iron deficiency is usually associated with thrombocytosis, thrombocytopenia may accompany severe iron deficiency in children and adults[315] (see Chapter 11). Anemia caused by folate or vitamin B_{12} deficiency (see Chapter 10) is also often associated with thrombocytopenia. Severe thrombocytopenia secondary to impaired hematopoiesis has been reported in association with anorexia nervosa.[316] The thrombocytopenia reverses with improved nutrition.

Thrombocytosis

Thrombocytosis is defined as a platelet count greater than 2 SD above the mean. Conditions associated with thrombocytosis in childhood are listed in Box 34-6.

When the platelet count is elevated, the clinician must determine whether the patient has a true increase in total body platelet mass. Under normal circumstances a third of the body's platelets are sequestered in the spleen. Individuals with surgical or functional asplenia who have a normal total body platelet mass will have an elevated platelet count. This situation is normal for an asplenic individual, and no therapy is warranted. Spuriously elevated automated platelet counts may be caused by the presence of microspherocytes, Pappenheimer bodies, red cell and leukocyte fragments, or bacteria.

Causes of true thrombocytosis fall into two categories: autonomous (or primary) thrombocytosis and reactive (or secondary) thrombocytosis. In primary thrombocytosis platelet production is unresponsive to normal regulatory processes.[317] The decrease in megakaryocyte size that normally results from an increase in platelet mass is not seen. In childhood most occurrences of thrombocytosis are secondary. In general, occurrences of reactive thrombocytosis are moderate in degree and asymptomatic and respond with treatment of the underlying disorder. Reactive thrombocytosis is often seen in association with inflammatory disorders (see Box 34-6). In these situations the degree of thrombocytosis usually parallels the activity of the underlying condition. Therapy to decrease the platelet count is not indicated. Iron deficiency is often associated with an increase in the platelet count (see Chapter 11). Moderate thrombocytosis that persists for 1 to 2 weeks occurs commonly after major trauma or surgery.[318]

Rarely, a child with thrombocytosis will have a primary myeloproliferative disorder such as essential thrombocythemia or chronic myelogenous leukemia. These patients may be predisposed to thrombosis or hemorrhage.

ACQUIRED DEFECTS IN PLATELET FUNCTION

Drug-Induced Platelet Dysfunction

Many substances have been shown to inhibit platelet function, including both prescription drugs and medicinals such as garlic and various Chinese herbs.[319,320] In otherwise normal individuals the impairment in platelet function produced by these substances is of no clinical significance. On the other hand, these agents may cause serious hemorrhage in patients with underlying coagulopathies, such as uremia, hemophilia, or thrombocytopenia, or in patients taking anticoagulants such as heparin or warfarin.[321]

Oxygenated metabolites of arachidonic acid, collectively termed eicosanoids, are involved in a variety of processes, including thrombosis, inflammation, and allergy. Eicosanoids include prostaglandins, thromboxanes, and other compounds. Interference with eicosanoid synthesis is the basis for the action of many therapeutic agents, including analgesics, antiinflammatory agents, and antithrombotic drugs. The first enzyme in the synthetic pathway of prostaglandins and thromboxanes is cyclooxygenase (COX). There are two isoforms of his enzyme, COX-1 and COX-2. The former is constitutively expressed in most cells, including platelets. The latter is not normally present but may be induced in certain cells after stimulation with cytokines or other factors. In platelets thromboxane X_2 (TxA_2) is the major product of COX. TxA_2 induces platelet aggregation and vasoconstriction. Aspirin blocks production of TxA_2 by covalently acetylating a serine residue near the active site of COX.[322] Because platelets do not synthesize new proteins, the action of aspirin is permanent and lasts the life of the platelet. Complete inactivation of platelet COX-1 is achieved when adults take 160 mg of aspirin daily. In pregnant women aspirin may cross the placenta and impair platelet function in the fetus.[323,324] Aspirin prolongs the bleeding time but seldom produces values above the normal range.

Most other antiinflammatory drugs act on platelets in a manner similar to that of aspirin, although the majority are less potent. Such agents include ibuprofen, naproxen, phenylbutazone, indomethacin, sodium salicylate, and related drugs. In contrast to those of aspirin, the effects of these medications are reversible.

Dipyridamole is a vasodilator that interferes with platelet function by increasing the intracellular concentration of cyclic adenosine monophophate (cAMP). This effect is mediated by inhibition of cyclic nucleotide phosphodiesterase.[325] In combination with warfarin, dipyridamole is used to inhibit embolization from prosthetic heart valves. Other drugs that raise cAMP levels by inhibiting phosphodiesterase, such as methylxanthines, also inhibit platelet function.

The thienopyridine derivative class of drug, including ticlopidine, inhibits platelet activation[326] and prolongs the bleeding time by blocking signaling through the $P2Y_{12}$ platelet adenosine diphosphate (ADP) receptor. Abnormal platelet function continues for several days after use of the drug is discontinued. A newer member of this class, clopidogrel, has supplanted ticlopidine because of its efficacy and better safety profile.[327-329]

Though used sparingly in pediatrics, GPIIb/IIIa antagonists are now widely used as anticoagulants in adult patients with heart disease.[330,331] These agents inhibit the final common pathway of platelet aggregation mediated by fibrinogen or VWF binding to GPIIb/IIIa. Therefore GPIIb/IIIa antagonists more completely inhibit platelet aggregation than aspirin or clopidogrel does, each of which inhibits only one initiating pathway of platelet activation (COX and ADP receptors, respectively). Several GPIIb/IIIa inhibitors are commercially available for use in coronary intervention procedures or unstable angina.[330,331]

A number of antibiotics inhibit platelet aggregation and the release reaction,[332] although the mechanisms are not well understood. Penicillin causes platelet dysfunction when administered at high doses, but this effect is usually clinically insignificant. However, certain semisynthetic penicillins, notably carbenicillin, may cause clinically significant bleeding when administered at the usual therapeutic doses.[333-336] Bleeding times are prolonged in patients receiving carbenicillin therapy, and serious episodes of hemorrhage have been reported.

Calcium channel blockers, such as verapamil and nifedipine, interfere with both adrenergic receptors and TxA_2 receptors in the platelet membrane[337] but do not prolong the bleeding time. Some antidepressants, including amitriptyline, imipramine, and chlorpromazine, interfere with platelet function through ill-defined effects on platelet membranes.[338] Propranolol and other β-adrenergic receptor antagonists mildly inhibit platelet function through effects on the cell membrane and serotonin transport.[339] Sulfonylureas used in the management of hyperglycemia have been associated with mild qualitative platelet defects.[340] Valproic acid, in addition to causing thrombocytopenia, can directly inhibit platelet function.[314]

Platelet Abnormalities Associated with Systemic Diseases

Uremia

Platelet dysfunction is a well-recognized and potentially serious complication of uremia. Patients with severe renal insufficiency may experience petechiae, purpura, gastrointestinal hemorrhage, and other forms of bleeding. Dialysis can correct the platelet dysfunction associated with uremia.[341] The precise cause of the platelet defect in uremia is unknown. A dialyzable substance in plasma causes platelet dysfunction, but the identity of this factor (or factors) remains controversial.

Bleeding may be severe, although the incidence of serious hemorrhage has declined in recent years because of more intensive dialysis and avoidance of drugs that further impair platelet function. If there is symptomatic bleeding or surgery is planned, patients should be treated with dialysis or desmopressin. Typically, only partial correction is achieved. The anemia of chronic renal insufficiency should be treated with erythropoietin because this has been shown to reduce the risk of serious bleeding.[341-346] If these approaches are not effective, cryoprecipitate may be added.

Liver Disease

Patients with liver disease have a multifactorial bleeding disorder. A reduction in plasma coagulation factors synthesized by the liver contributes to the increased risk of bleeding in these patients. Moderate thrombocytopenia is a common finding in liver disease and is well tolerated in most instances. Thrombocytopenia in cirrhotic liver disease has long been ascribed to portal hypertension and concomitant hypersplenism. Recent studies suggest that altered thrombopoietin production may contribute to the thrombocytopenia in liver disease. Qualitative platelet defects have also been reported to occur in adult patients with liver failure,[347-350] although the mechanisms responsible are not well understood.

Box 34-7 Vascular Purpuras of Childhood

- Vasculitis
  - Henoch-Schönlein purpura
  - Kawasaki syndrome
  - Polyarteritis nodosa
- Purpura fulminans
- Connective tissue diseases
  - Ehlers-Danlos syndrome
  - Marfan syndrome
  - Osteogenesis imperfecta
  - Minkes disease
  - Pseudoxanthoma elasticum
- Hereditary hemorrhagic telangiectasia

Vascular Purpuras

The vascular purpuras, also termed the *nonthrombocytopenic purpuras,* are mentioned in this chapter because these diseases share features with ITP. These conditions often follow acute infection. A list of childhood vascular purpuras is presented in Box 34-7.

Henoch-Schönlein Purpura. Henoch-Schönlein purpura (HSP), also known as allergic purpura or anaphylactoid purpura, is a vasculitis affecting capillaries of the skin, synovial membranes, renal mesangium, and small intestine. The purpuric manifestations of the disease are usually self-limited.

HSP is presumably the result of an autoimmune process. The basic lesion is a microvasculitis with endothelial cell injury. Deposits of IgA are evident on capillary endothelial cells of the skin, kidney, and gastrointestinal tract. The renal manifestations of HSP are indistinguishable from those of so-called IgA nephropathy.[351]

The median age at diagnosis is 5 years (range, 0.4 to 15 years). Males predominate at a ratio of 3 : 2. An acute febrile illness precedes the syndrome in a majority of cases. In about 50% of patients, raised purpuric papules (palpable purpura) are evident over the lower extremities and buttocks, whereas in the remainder of patients the purpuric rash is more extensive.[352] Bullae, urticaria, diffuse erythema, and ulceration may also be seen. Joint pain or swelling is evident in about 80% of cases. Two thirds of patients exhibit abdominal signs or symptoms, including pain, hematemesis, or melena. Intussusception occurs in about 4% of patients with HSP. Edema, including scrotal swelling, is common. Renal involvement is evident in 40% of patients, many of whom exhibit severe proteinuria. The manifestations of this syndrome resolve within 1 to 6 weeks in the vast majority of patients. In a small subset of patients, permanent renal or joint damage may ensue.[353]

Glucocorticoid therapy can reduce the skin, joint, and gastrointestinal manifestations of the disease but should be reserved for those with severe symptoms. There is little evidence that glucocorticoids prevent renal involvement[354,355] or intussusception.

Purpura Fulminans. Purpura fulminans is a potentially fatal disorder that follows infection with meningococcus, streptococcus, varicella, and rubella. Thrombosis of small arterioles leads to infarction and hemorrhage of skin, subcutaneous tissues, and muscle. The disease occurs suddenly 2 to 4 weeks after a relatively mild infection such as varicella or scarlet fever. It begins with purpuric lesions on the skin that coalesce and then become necrotic. Patients become extremely ill with fever, hypotension, and laboratory evidence of DIC. The disease resembles pupura fulminans neonatalis, a disorder associated with homozygous protein C or protein S deficiency (see Chapter 33).

CHAPTER 35

Acquired Disorders of Hemostasis

Steven Pipe and Neil Goldenberg

CHAPTER OUTLINE

ACQUIRED HEMORRHAGIC DISORDERS
Drug-Induced Bleeding
Disseminated Intravascular Coagulation
Liver Disease
Vitamin K Deficiency
Massive Transfusion Coagulopathy
Acquired Inhibitors of Coagulation Proteins
Acquired Inhibitors to Prothrombin—Hemorrhagic Lupus Anticoagulant Syndrome
ACQUIRED THROMBOEMBOLIC DISEASE
Characterization of Thromboembolism in Children
Venous Thromboembolism
Ischemic Arterial Stroke

ACQUIRED HEMORRHAGIC DISORDERS

Chapter 29 describes how the application of clinical skills forms the cornerstone for the assessment of a potential bleeding disorder. After confirming that a bleeding disorder is present through a comprehensive medical history and physical examination, the clinician should next address whether the condition is likely familial or acquired. This is sometimes difficult because some patients with mild underlying heritable hemostatic defects (e.g., mild von Willebrand disease [VWD] or platelet function defects) may not demonstrate suspicious clinical symptoms until faced with a traumatic injury or a surgical challenge at a later age. Nevertheless, acquired bleeding disorders remain a frequent clinical scenario, with presentations ranging from acute unexpected bleeding during or immediately after surgery to unusual or excessive clinical manifestations of bruising, petechiae, epistaxis, gum bleeding, or hematoma formation that occur over weeks to months. Distinguishing whether the bleeding most likely represents an abnormality in primary hemostasis, fibrin formation, or fibrinolysis provides a framework for the generation of a differential diagnosis (See Chapter 29). For example, petechiae are almost exclusively seen with defects in platelet number or function, whereas deep tissue hematomas are more likely associated with defects in fibrin formation, as would occur with clotting factor deficiencies. Standard screening laboratory tests such as the prothrombin time (PT) and activated partial thromboplastin time (aPTT) are most often used in the initial evaluation but are insensitive to mild but clinically significant reductions in hemostatic capacity.[1] In addition, a platelet count does not provide any assessment of platelet function. Therefore the clinician must rely on the history and physical findings to guide the extent of additional coagulation studies. The most common causes of acquired hemorrhagic disorders include drug-induced bleeding (e.g., anticoagulants); disseminated intravascular coagulation; liver disease; vitamin K (VK) deficiency; massive transfusion; renal disease; and, rarely, acquired inhibitors to coagulation proteins.

Drug-Induced Bleeding

Many drugs have been associated with abnormal platelet function, although not all result in bleeding manifestations. The major classes include antiinflammatory agents, antibiotics, cardiovascular drugs, psychotropic drugs, anticonvulsants, and anticoagulants. Aspirin is the commonest example, acting by irreversibly acetylating a serine residue at the active site of cyclooxygenase,[2] whereas other nonsteroidal antiinflammatories (e.g., ibuprofen, naproxen) are reversible inhibitors.[3] β-Lactam antibiotics can interfere with platelet function through binding to the platelet membrane.[4,5] Calcium channel blockers (e.g., nifedipine)[6] and tricyclic antidepressants, such as amitriptyline,[7] can result in decreased platelet aggregation responses but are unlikely to result in clinical bleeding. Valproic acid has become one of the most commonly used anticonvulsants in children. Interestingly, several mechanisms of relevant valproate-induced coagulopathies have been described, including thrombocytopenia and platelet dysfunction, acquired VWD, decreased VK-dependent clotting factors, hypofibrinogenemia, and decreased factor XIII levels.[8] Therapeutic anticoagulants (heparin, low-molecular-weight heparin, warfarin, and direct inhibitors of factor Xa and thrombin) should be the most readily apparent cause of drug-induced bleeding and in most patients can be correlated with laboratory monitoring. Platelet receptor antagonists (IIb/IIIa inhibitors; e.g., abciximab, eptifibatide, tirofiban, and adenosine diphosphate receptor antagonists; e.g., clopidogrel) are in increasing use in patients with congenital heart disease and patients undergoing interventional studies.[9]

In most cases discontinuation of the offending drug should resolve the hemorrhagic manifestations, but this will depend on the reversibility and half-life of the drug. VK administration will in most cases rapidly reverse warfarin-induced bleeding. Alternatively, when more rapid replacement is necessary to correct low levels of factors II, VII, IX, and X, infusion with a prothrombin complex concentrate (PCC) or fresh frozen plasma (FFP) can be considered. PCCs are formulated with either three factors (II, IX, and X) or four factors (II, VII, IX, and X) and have some advantages over FFP. PCCs can be rapidly reconstituted in small infusion volumes, have a fast onset of action, do not require identification of the patient's blood group, have an exceptional safety profile with respect to risk of viral transmission owing to pathogen reduction and inactivation steps incorporated into their manufacturing, and reduced risk of adverse reactions such as transfusion-associated circulatory overload or transfusion-associated acute lung injury.[10] A four-factor PCC, Kcentra, was recently approved by the U.S. Food and Drug Administration (FDA) for the urgent reversal of acquired coagulation factor deficiency induced by VK antagonism therapy in adults with acute major bleeding. Transfusions of fresh platelets are indicated in those patients with life-threatening or unremitting bleeding caused by drug-induced platelet dysfunction. In cases of minor bleeding in which the drug cannot be readily discontinued (e.g. anticonvulsants), desmopressin has been used with some success.[11]

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a pathologic syndrome in which the normal physiology of coagulation is disturbed by the simultaneous action of four mechanisms: increased thrombin generation, suppressed physiologic anticoagulant pathways, activation and subsequent impairment of fibrinolysis, and activation of the inflammatory pathway.[12] This leads to widespread intravascular deposition of fibrin with resultant thrombotic end-organ complications and consumption of platelets and coagulation proteins, resulting in severe bleeding. Associated damage to the microvasculature can contribute to organ dysfunction, capillary leak, and shock.

Etiology

DIC is always a secondary phenomenon and not a disease entity in its own right. Thus its recognition should prompt the clinician to identify and treat the underlying cause rather than merely react to the bleeding manifestations. It most frequently occurs in the settings of sepsis, trauma, and systemic inflammatory syndrome, with an approximate frequency in hospitalized children of 0.4% to 1%, with sepsis accounting for approximately 95% of cases.[13,14] It is primarily a clinical diagnosis based on the evaluation of laboratory results in patients with a clinical condition known to be associated with DIC (Box 35-1).

Box 35-1 Causes of Disseminated Intravascular Coagulation

INFECTIOUS

Meningococcemia (purpura fulminans)
Other gram-negative bacteria (Haemophilus, Salmonella)
Gram-positive bacteria (group B Streptococcus)
Rickettsia (Rocky Mountain spotted fever)
Viruses
Malaria
Fungus

TISSUE INJURY

Central nervous system trauma (massive head injury)
Multiple fractures with fat emboli
Crush injury
Profound shock or asphyxia
Hypothermia or hyperthermia
Massive burns

MALIGNANCY

Acute promyelocytic leukemia
Acute monoblastic or myelocytic leukemia
Widespread malignancies (neuroblastoma)

VENOM OR TOXIN

Snake bites
Insect bites

MICROANGIOPATHIC DISORDERS

"Severe" thrombotic thrombocytopenic purpura
Hemolytic-uremic syndrome
Giant hemangioma (Kasabach-Merritt syndrome)

GASTROINTESTINAL DISORDERS

Fulminant hepatitis
Severe inflammatory bowel disease
Reye syndrome

HEREDITARY THROMBOTIC DISORDERS

Homozygous protein C deficiency

MISCELLANEOUS

Severe graft rejection
Acute hemolytic transfusion reaction
Severe collagen-vascular disease
Kawasaki disease
Heparin-induced thrombosis
Infusion of "activated" prothrombin complex concentrates
Hyperpyrexia/encephalopathy, hemorrhagic shock syndrome

From Colman R, Marder V: Disseminated intravascular coagulation (DIC): pathogenesis, pathophysiology, and laboratory abnormalities. In Colman R, Marder V, Salzman E, editors: Hemostasis and thrombosis: basic principles and clinical practice. *Philadelphia, 1982, JB Lippincott, p. 654.*

Clinical Presentation

The clinical manifestations of DIC include bleeding, thrombosis, or both, however typically bleeding predominates. Early indicators are bleeding resulting from venipunctures, intravascular accesses, and surgical wounds. Mucocutaneous bleeding may manifest as bruising, petechiae, epistaxis, gum bleeding, blood from tracheal aspirates, gastrointestinal bleeding, and hematuria. In fulminant cases it may lead to bleeding into vital organs. However, with increasingly sensitive diagnostic tests that can detect endogenous activation of the hemostatic process, the clinical spectrum of DIC is broad. Nonovert DIC describes a stressed but compensated hemostatic system, in which the laboratory tests are abnormal but there are no clinical manifestations.[15] Overt DIC is described as a stressed and decompensated hemostatic system, in which the laboratory tests are abnormal and clinical bleeding or microvascular thrombosis and organ dysfunction exists. Overt DIC may be controlled or uncontrolled depending on whether the process will resolve when the underlying stimulus is removed.

Diagnosis

The clinical presentation of a profoundly ill child with bleeding believed to be secondary to DIC can be supported by laboratory tests showing evidence of a consumptive coagulopathy with activation of the fibrinolytic cascade. Moderate to severe thrombocytopenia with or without anemia will be evident from the complete blood count. Thrombocytopenia is present in approximately 50% of patients and suggests consumption of platelets.[16] Anemia could be caused by bleeding or, when accompanied by schistocytes on blood smear, evidence of microangiopathic hemolytic anemia. The PT and aPTT are prolonged in 50% to 60% of patients,[17] reflecting consumption of many coagulation proteins, including prothrombin; factors V, VII, and VIII; and fibrinogen. Fibrinogen or fibrin degradation products (FDPs) and D-dimers are both increased in concentration in most patients with DIC, suggesting activation of the fibrinolytic process.[18] Marked reductions in plasma anticoagulants including proteins C and S and antithrombin (AT) have also been described.[12,19] The most sensitive tests for diagnosis of DIC are markers of endogenous thrombin generation: prothrombin fragment 1.2 and thrombin-AT (TAT) complexes.[20] Prothrombin fragment 1.2 is released when thrombin is generated from prothrombin. TAT complexes are generated by binding of thrombin with its inhibitor AT. The standard assays (PT, aPTT, platelet count, and D-dimers) are relatively rapid and simple to perform. However, changes in these test results do not always occur at the same time, and laboratory values change rapidly depending on the patient's clinical status. This may create confusion in patient management and make the diagnosis of DIC at an early stage particularly difficult. The International Society on Thrombosis and Haemostasis (ISTH) diagnostic scoring system for overt DIC has been widely used in intensive care units, and several publications have validated the score against morbidity scores.[15,21,22] The five-step algorithm assigns a score based on the severity of abnormality for each of the following: platelet count (>100 × 109/L = 0; <100 × 109/L = 1; <50 × 109/L = 2), elevated fibrin-related markers (no increase = 0; moderate increase = 2; strong increase = 3), prolonged prothrombin time (<3 seconds = 0; <3 seconds but <6 seconds = 1; >6 seconds = 2), and fibrinogen level (>1 g/L =0; <1 g/L = 1). A total score of 5 or more is considered compatible with overt DIC. The sensitivity and specificity of this scoring system are greater than 90%. However, the algorithm should be applied only in the presence of an underlying disorder known to be associated with DIC. Despite its use in many pediatric intensive care units in the United States, there remains a paucity of clinical research studies examing the utility of the ISTH scoring system in children. Investigators at Texas Children's Hospital have compared their institutional modified DIC criteria with the ISTH diagnostic score against a gold-standard diagnostic method of confirmation of DIC in a subset of children who died.[23] Their modified criteria is not a scoring system but a sequential analysis of coagulation assays (PT, platelet count, fibrinogen, and D-dimer) as evaluated by transfusion medicine specialists along with the patient's clinical condition. Such an approach yielded a higher sensitivity, owing to the inclusion of sequential testing, to recognize a trend in the evolution from an early-phase DIC to overt DIC.

Treatment

The fundamental principal of DIC treatment is the specific and vigorous treatment of the underlying disorder. In some cases DIC will completely resolve within hours after resolution of the underlying condition (e.g., appropriate control of sepsis with antimicrobials). However, in other cases supportive measures are required to control the DIC until the underlying condition is resolved (e.g., the use of all-*trans*-retinoic acid and chemotherapy for the treatment of acute promyelocytic leukemia and DIC.[24]) Therapeutic interventions remain controversial and must be individualized according to the underlying basis for the DIC and severity of the clinical symptoms. For example, in nonovert DIC, children do not usually require therapy for the DIC itself. However, in the presence of uncontrolled overt DIC, therapeutic intervention including blood replacement products may be indicated to improve hemostasis while waiting for effective therapy for the underlying condition. Treatment modalities investigated include blood component therapy, anticoagulants, restoration of natural anticoagulant pathways, and other agents.

Blood Component Therapy. In general, the more severe the laboratory abnormalities, in particular the degree of thrombocytopenia and coagulation factor depletion, the greater the risk of bleeding complications with DIC. Hence treatment with FFP, fibrinogen, cryoprecipitate, and platelets appears to be a rational therapy in bleeding patients or patients who are at risk for bleeding with a significant depletion of these hemostatic factors. However, blood component therapy should not be instituted on the basis of laboratory results alone; it is indicated only in patients with active bleeding, those who require an invasive procedure, or those who are otherwise at risk for bleeding complications.[25] Large volumes of plasma (15 to 30 mL/kg) may be necessary to correct the coagulation defect. PCC may be considered in actively bleeding patients if FFP transfusion is not possible. However, these products lack certain essential coagulation factors, such as factor V. The efficacy and safety of recombinant factor VIIa in DIC with life-threatening bleeding are unknown.

Reasonable goals are to maintain platelet counts above 50×10^9/L, fibrinogen concentrations above 1.5 g/L, and PT values less than double the normal range.

Anticoagulant Therapy. Considering the central role played by thrombin in DIC, the use of heparin or other anticoagulants to inhibit thrombin generation appears reasonable. Heparin can at least partly inhibit the activation of coagulation in sepsis and other causes of DIC.[26] However, a beneficial effect of heparin on clinically important outcome events in patients with DIC has never been demonstrated in controlled clinical trials and is not a standard of care in overt cases of DIC. However, therapeutic doses of heparin may be indicated in patients with clinically overt thromboembolism, chronic DIC, or extensive fibrin deposition such as seen in purpura fulminans or acral ischemia.[27]

Replacement of Natural Anticoagulant. Depleted levels of AT, protein C, and protein S cannot be effectively replaced with FFP alone because of the short plasma half-life of these proteins. AT and protein C concentrates have been extensively evaluated in patients with DIC.[28-32] Trials of AT therapy have not yet provided conclusive evidence sufficient to make treatment recommendations.[33] The double-blind, placebo-controlled, phase III trial of recombinant human activated Protein C Worldwide Evaluation in Severe Sepsis (PROWESS) demonstrated a significant decrease in mortality for the protein C–treated group compared with placebo.[31] However, these findings were not replicated in later trials, treatment was associated with a higher risk of bleeding, and recombinant human protein C was ultimately withdrawn in 2011.[34] Soluble recombinant human thrombomodulin acts by reducing thrombin-mediated clotting, enhancing protein C activation at the site of clotting, as well as demonstrating some antiinflammatory properties. However, a large randomized controlled trial failed to demonstrate a benefit in 28-day mortality rates.[35]

Other Agents. Recently, recombinant factor VIIa (rVIIa) has become an attractive strategy to control bleeding in various scenarios.[36] In situations where volume overload is an issue or bleeding persists despite adequate blood component support, use of rVIIa has been shown to be effective.[37] However, these data have mostly been generated from anecdotal reports, and given the potential adverse thrombotic complications with this agent, controlled randomized trials are required to address its safety and efficacy in these patients. Antifibrinolytic agents can be effective in bleeding patients, but the use of these agents in patients with bleeding associated with DIC is generally not recommended. They could be considered in cases when hyperfibrinolysis is suspected, such as may occur with acute promyelocytic leukemia or trauma.[38]

Liver Disease

Pathophysiology

The liver is the main site of synthesis for most hemostatic components. However, the hemostatic impairment in liver disease involves a variety of mechanisms, including impaired hepatic synthesis, activation of the coagulation and fibrinolytic systems, poor clearance of activated hemostatic components, loss of hemostatic proteins into ascitic fluid, concurrent VK deficiency, thrombocytopenia, and impaired platelet function.[39,40] When both procoagulants and anticoagulants are reduced, hemostatic dysregulation results in both a propensity to hemorrhage and a propensity to thrombose. Along with reduced synthesis there may be secretion of abnormal forms of the hemostatic proteins that may function as inhibitors to coagulation. For example, abnormal fibrinogens (dysfibrinogenemias) are very common in liver disease.[41] Similarly, VK-dependent proteins (factors II, VII, IX, X, protein C, protein S, and protein Z) decrease in liver disease. However, they may also be secreted in forms with abnormal gamma-carboxylation reactions of the glutamic acid residues on the amino-terminal portion of the protein leading to reduced functional activity.[42] Hypofibrinogenemia may be related to decreased synthesis, or increased consumption (e.g., DIC). However, in patients with acute liver failure, plasminogen activator inhibitor (PAI-1) is increased, shifting the balance toward hypofibrinolysis. This occurs despite elevated levels of tissue plasminogen activator (tPA) that may be secondary to increased release from the activated endothelium or reduced clearance by the diseased liver (or both). The other proteins involved in fibrinolysis (plasminogen, α2-antiplasmin, thrombin activatable fibrinolysis inhibitor, and factor XIII) are typically reduced because of decreased liver synthesis.[43] In addition, several structural manifestations of liver disease can contribute to the bleeding in these patients, including portal hypertension, varices, gastritis, and hemorrhoids.

Clinical Presentation

Clinical symptoms are variable and dependent, to some extent, on the etiology of the liver failure and associated invasive procedures. Symptoms include ecchymosis and petechiae, mucous membrane bleeding, hemorrhage from gastrointestinal varices, and hemorrhage into the abdomen or central nervous system (CNS). However, clinically significant bleeding occurs rarely in acute liver failure (approximately 5% to 10% of cases).[43] Coagulation screening tests (aPTT, PT, thrombin clotting time) are usually prolonged, platelet counts are reduced, and bleeding time is prolonged. Plasma concentrations of FVII; FV; and, less commonly, fibrinogen are decreased.[39] Levels of FVIII may be normal or elevated, possibly reflecting reduced clearance via low-density-lipoprotein receptor-related protein,[44] and can be helpful in distinguishing severe liver disease from DIC. However, both conditions may occur simultaneously.[45] FDPs or D-dimer levels are often increased in hepatic failure and contribute to prolongation of the thrombin clotting time and impaired platelet function.[46] Dysfibrinogenemia will contribute to prolongations of the PT and aPTT, but the thrombin time and reptilase assays are more sensitive. Dysfibrinogenemia may be confirmed by demonstrating an abnormal ratio of clottable fibrinogen (functional assay) to fibrinogen antigen (immunoassay).

Treatment

Treatment for the hemostatic manifestations of severe hepatic failure is difficult. Enhanced hemostasis after replacement therapy is usually transient because adequate volumes of FFP cannot be infused, owing to associated hypervolemia. In addition, many coagulation proteins are rapidly cleared, thereby limiting any beneficial effect. Usually, therapy specifically directed at the coagulopathy is reserved for active bleeding or to facilitate invasive procedures. A common indication for FFP is an international normalized ratio (INR) greater than 2 or a PT prolongation greater than 4 seconds.[47] However, there are no firm guidelines, and some interventions may safely be performed with INR in the 2 to 2.5 range.[48] Although desmopressin can induce the release of factor VIII and von Willebrand factor (VWF) with a shortening of the bleeding time, in randomized trials desmopressin failed to control bleeding from acute variceal hemorrhage[49] or decrease blood loss with hepatectomy.[50] Cryoprecipitate can be administered to increase plasma fibrinogen concentrations if necessary. Secondary VK deficiency owing to impaired VK utilization or impaired VK absorption owing to cholestasis from intrahepatic and extrahepatic biliary atresia requires treatment with VK.[51] Isovolumetric plasmapheresis may aid in restoration of hemostasis by replacing coagulation factors while removing activated clotting factors, tPA, fibrin, and FDPs.[52] Recombinant VIIa has been shown to correct the prolonged PT in nonbleeding cirrhotic patients and has been used to avoid volume overload before invasive procedures likely to cause bleeding. However, randomized trials in the setting of liver biopsy and variceal bleeding have shown either no difference in hemostasis or only early, modest reductions in rebleeding rate but no difference in overall bleeding or transfusion requirements.[42] Larger studies are still required to evaluate the efficacy and safety of this agent in liver disease.

Patients requiring liver transplantation invariably have severe, end-stage hepatic failure with its associated hemorrhagic complications. Additional risk factors that contribute to bleeding in children during transplantation include extensive scar tissue from previous surgery, prolonged duration of the surgery, the need to reduce the size of the donor organ to fit the small patient, dilutional coagulopathy, and excessive activation of the fibrinolytic system during the anhepatic phase.[53-56] Although treatment with antifibrinolytic agents is an attractive option, this approach should be used with caution because children who undergo liver transplant may later develop either hemorrhagic or thrombotic complications. The prophylactic use of recombinant VIIa to reduce blood loss and transfusion requirements in patients undergoing liver transplantation has been studied in two multicenter randomized controlled trials.[57,58] These trials failed to demonstrate a benefit to support its use as a universal preemptive therapy for liver transplantation.[59] Recombinant VIIa could be considered in individual cases as “rescue therapy” for patients with life-threatening coagulopathy and bleeding during transplantation or in situations where blood products are unavailable or unacceptable (e.g., the Jehovah witnesses).[60]

Vitamin K Deficiency

The role of VK in coagulation is detailed in Chapter 27, and VK deficiency bleeding in newborns is discussed in detail in Chapter 29.

Clinical Presentation

Clinical symptoms of VK deficiency include mild to moderate bleeding; ecchymoses; oozing from intravenous (IV) puncture sites; and, rarely, internal bleeding. The primary disorder is usually identified on the basis of the history and physical examination.

Primary VK deficiency in healthy children is uncommon because of a relatively low VK requirement and the widespread distribution of VK in plant and animal tissues. In plants the only important molecular form is phylloquinone (VK1). Bacteria synthesize a family of vitamin K compounds called menaquinones (VK2). The contribution of the microbiologic flora of the gut to VK dietary intake is unknown but may be as high as 50%.[61] Although broad-spectrum antibiotics may reduce VK2 production by intestinal bacteria, VK deficiency is rare in the presence of a normal diet.

Groups of children at high risk for VK deficiency include breastfed newborns, chronically ill children with an inadequate dietary intake of VK, children with disorders that interfere with the absorption of VK (e.g., diarrhea, cystic fibrosis, cholestatic liver disease, celiac disease), and children with poor nutrition who are receiving broad-spectrum antibiotics.[62-65] Cystic fibrosis, biliary atresia, and obstructive jaundice interfere with the absorption of fat-soluble vitamins and interfere with transport to the liver, with resultant VK deficiency. Therapeutic drugs can interfere with VK metabolism (e.g., phenytoin, warfarin). However, at least in the case of warfarin administration, this is an expected side effect. Accidental exposure to supratherapeutic doses may occur in small children with access to warfarin in the home. Anticoagulant rodenticides can be another source of accidental exposure. Owing to the emergence of warfarin-resistant strains of rats, newer “long-acting” second-generation compounds have been utilized. These so-called “superwarfarins” have higher affinity for vitamin K1-2,3 epoxide reductase, are able to disrupt the vitamin K1-epoxide cycle at more than one point, exhibit hepatic accumulation, and have unusually long biological half-lives as a result of their high lipid solubility and enterohepatic circulation. After accidental ingestion these compounds can cause anticoagulation for several days or even weeks. However, in most cases involving small children, the exposure is low and bleeding manifestations are rare.[66,67] VK deficiency has been described in bone marrow transplant and oncology patients in whom the etiology is multifactorial as a result of drug antagonism, liver dysfunction, fat malabsorption, anorexia, or inadequate dietary intake. A study of children evaluated before undergoing bone marrow transplantation identified 31% (8 of 26) with evidence of VK deficiency (as evidenced by circulating PIVKA-II), although only one patient had a prolonged PT, highlighting that the PT alone is an insensitive marker of VK deficiency. Of the eight affected patients, six exhibited bleeding manifestations peri-transplant.[68]

Laboratory Diagnosis

The PT and aPTT may both be abnormal in VK deficiency but should correct in a 1:1 mix with normal plasma. Other acquired or congenital coagulopathies can give similar screening test abnormalities. Therefore specific coagulation factor assays must be performed. The finding of more than one VK-dependent factor deficiency should increase the suspicion of an acquired deficiency. A normal factor V in addition to normal liver function studies would suggest that there is no significant liver disease underlying the presentation. A normal FVIII and fibrinogen level and absence of elevated D-dimers would make DIC unlikely. However, VK deficiency can complicate other coagulopathies, such as DIC or liver disease. If there is any doubt about the diagnosis, the patient should receive VK therapy in conjunction with other supportive care.

Treatment

The route and specific type of therapy are dictated by the urgency of the clinical situation and potential side effects of therapy. For example, severe anaphylactoid reactions, although rare, have complicated IV VK administration, even when the solution is diluted and infused slowly. Therefore IV administration of VK, at a rate no faster than 1 mg per minute, should be restricted to those situations in which other routes are not feasible and the risk is justified. Intramuscular VK is not recommended because it can result in pain, swelling, and hematoma formation. The preferred systemic route is subcutaneous because it is safe and effective. Oral VK is effective if absorption is unimpaired. Although oral administration is generally thought to produce a slower correction of the PT (6 to 8 hours) compared with parenteral VK (2 to 6 hours), a study in adults suggested that the oral route may actually be faster, at least in reversing the effect of warfarin.[69]

Asymptomatic patients with mildly abnormal coagulation results that are presumed secondary to VK deficiency should be given VK subcutaneously (1 to 5 mg depending on size). This approach is both therapeutic and diagnostic, with coagulation abnormality correction within 2 to 6 hours. A patient bleeding because of VK deficiency should receive 2 to 10 mg of VK subcutaneously. FFP (10 to 20 mL/kg) is particularly useful when the precise nature of the coagulopathy is unknown and bleeding is severe. However, the amount of plasma needed for total correction of a severe VK deficiency is so great that it may result in volume overload. A patient with a life-threatening hemorrhage or an intracranial hemorrhage (ICH) would likely benefit from prothrombin complex concentrates at a minimum dose of 50 units/kg, in addition to systemic VK (5 to 20 mg). Prothrombin complex concentrates contain relatively uniform amounts of factors II, IX, and X, with amounts of factor VII/VIIa varying.[70] Recombinant VIIa has been used anecdotally.[71,72]

Prevention

Prophylactic VK should be given to patients at risk, such as patients with inadequate nutrition and those who are receiving broad-spectrum antibiotics. Most patients requiring total parenteral nutrition (TPN) are supplemented with VK. There has been concern in the past that maternal anticonvulsant therapy may be associated with increased risk of neonatal bleeding linked to enzymatic degradation of VK.[73] This has prompted recommendations for VK prophylaxis to pregnant mothers on anticonvulsants. However, recent studies have demonstrated that the incidence of bleeding in infants exposed to these drugs antenatally is not higher than controls[74] and have shown no benefit to routine VK prophylaxis.[75]

Massive Transfusion Coagulopathy

Uncontrolled bleeding can be a clinical problem associated with the management of trauma and surgical patients, often necessitating the transfusion of large amounts of blood and blood derivatives. Massive transfusion has been commonly defined as replacing at least one blood volume in 24 hours or 50% of one blood volume in 3 hours.[76,77] Criteria used by the University of Michigan Hospitals for adults is 4 U of red blood cells utilized in less than 4 hours and ongoing uncontrolled bleeding, and for children 30 mL/kg of red blood cells utilized and ongoing uncontrolled bleeding. Patients with this degree of bleeding will develop defective hemostasis related to the transfusions in addition to the underlying precipitating trauma or surgical insult. The resulting bleeding diathesis may be complex and may include evidence of DIC; depletion of hemostatic factors through blood loss, tissue injury, and consumption of factors; dilutional coagulopathy owing to aggressive blood component resuscitation; hypothermia; platelet dysfunction; and excessive fibrinolysis.[76] Hemostatic resuscitation advocates for the transfusion of red blood cells, plasma, and platelets in a 1:1:1 ratio in order to address the underlying dilutional coagulopathy. Massive transfusion protocols are now utilized worldwide for patients with severe life-threatening bleeding and are intended to standardize the approach to these patients and provide structure and organization to what is usually a chaotic situation. These protocols standardize the ratio for blood products that are empirically delivered; initiate unique communication processes among the blood bank, the clinical laboratories, and the clinician; and call attention to appropriate management of acidosis, hypothermia, and hypocalcemia that may be aggravating the coagulopathy. Clinical studies with massive transfusion protocols have demonstrated decreased crystalloid use, improved survival rates, decreased chance of organ failure, and decreased risk of early death resulting from hemorrhage. Fibrinogen concentrates for acquired fibrinogen deficiency have been evaluated by postmarketing surveillance studies and retrospective analyses and show results consistent with in vitro studies demonstrating that fibrinogen replacement can improve clot firmness and improve survival of severely injured massively bleeding patients. Recombinant factor VIIa has been evaluated in several randomized clinical trials for bleeding in the context of trauma and surgery but has failed to improve outcomes.[78,79]

Acquired Inhibitors of Coagulation Proteins

Inhibitors directed against coagulation factors are circulating antibodies that specifically neutralize the procoagulant activity or increase the clearance of those coagulation factors leading to a plasma deficiency and are often accompanied by bleeding manifestations.[80,81] They may be either alloantibodies or autoantibodies. Examples of alloantibodies include those directed against infused factor VIII and are observed in 15% to 25% of patients with hemophilia A (discussed in Chapter 31). Autoantibodies have also been observed directed against endogenous factor VIII in nonhemophiliacs and occur typically in postpartum women, elderly individuals, or people who have autoimmune disorders. However, autoantibodies have also been ascribed to other coagulation proteins, including fibrinogen; factors II, V, VII, IX, X, XI, and XIII; andVWF. Antiphospholipid antibodies (APLAs), or lupus anticoagulant (LA), are a heterogeneous group of antibodies that react with proteins bound to phospholipids. Although these primarily function as inhibitors to in vitro phospholipid-dependent clotting assays, they paradoxically predispose to thrombosis rather than hemorrhage. However, a unique LA coagulopathy has been observed with a hemorrhagic syndrome associated with hypoprothrombinemia (discussed later).

Acquired Inhibitors to Factor VIII

Anti–factor VIII autoantibodies are rare in children but can result in severe bleeding and significant morbidity. They are associated with underlying medical conditions in half of those affected, including malignancy, autoimmune disease, lymphoproliferative disorders, and drugs (e.g., penicillin).[82] Patients can present with bleeding symptoms ranging from easy bruising to intracranial hemorrhage. In one patient the clinical course was also complicated by nephrotic syndrome.[83] Laboratory screening studies will show a prolonged aPTT that does not fully correct on mixing with normal plasma in a 1 : 1 mix ("Inhibitor Screen"). In addition, this can be distinguished from an LA by performing the aPTT 1 : 1 mix again with an incubation phase (typically at least 30 minutes at 37° C) in which the aPTT will show further prolongation indicating progressive neutralization of factor VIII provided by the normal plasma mixing. There will be no significant additional prolongation seen on incubation in the presence of an LA. In contrast to congenital hemophilia with inhibitors, these antibodies typically demonstrate type II (nonlinear) inactivation kinetics. Thus the baseline factor VIII levels may be higher than 1% despite high titer inhibitory antibodies.[84]

Treatment is two-pronged, directed at stopping the bleeding and eradicating the inhibitor. Hemostasis can be achieved with high doses of factor VIII concentrates, activated prothrombin complex concentrates (APCC), and recombinant VIIa. Immunosuppression may be accomplished with steroids alone or in combination with mycophenolate-mofetil, rituximab, γ-globulin, or cytotoxic agents such as cyclophosphamide.[85,86] Inhibitors have also been eradicated through extracorporeal immunoadsorption and immune tolerance with regular exposure to high-dose factor VIII infusions. Review of the available literature suggests that, in contrast to adults, anti–factor VIII autoantibodies in children may resolve more quickly and easily and do not necessarily require steroids and cytotoxic agents.[82,86,87] Recombinant factor VIII should be considered in the initial treatment with additional hemostatic support from APCCs and recombinant VIIa as needed. Withdrawal of instigating drugs such as penicillin may also facilitate resolution.[88]

Acquired Inhibitors to Factor IX

Few cases of spontaneous factor IX inhibitors have been described in nonhemophiliac patients, and most adult cases have been related to underlying systemic disorders such as systemic lupus erythematosus, hepatitis, multiple sclerosis, rheumatic fever, collagen vascular disease, postpartum status, and postprostatectomy status. Reports in children are limited to a few case reports.[86,89-91] Bleeding manifestations included cutaneous ecchymoses and soft tissue hematomas. Diagnostic studies are similar to those with anti–factor VIII inhibitors. Treatments have included corticosteroids, γ-globulin, and cyclophosphamide, with rapid resolution of the inhibitor. One child had a spontaneous resolution.[90] Recombinant factor IX and recombinant VIIa can be considered for acute management of bleeding.

Acquired Inhibitors to Factor V

Most cases of inhibitors directed against factor V develop as a result of risk factors such as surgical procedures, antibiotic administration (typically the β-lactam group), blood transfusions, cancers, and autoimmune disorders. However, the majority of cases arise after exposure to bovine thrombin.[81] Topical preparations of bovine thrombin are widely used for surgical hemostasis and contain fibrinogen as well as small amounts of factor V and other proteins. Acquired inhibitors to coagulation factors, as a consequence of exposure to this highly immunogenic agent, is a frequent occurrence, albeit often unrecognized. In this context antibodies directed against factor V are most frequent, although anti-prothrombin and anti–factor X antibodies have also been described.[92,93] The incidence of symptomatic inhibitors is not known. In a study of 151 adult patients exposed to bovine thrombin during cardiac surgery, 56% of the patients developed antibodies directed against human coagulation proteins.[92] However, adverse clinical outcomes did not correlate with antibody formation. A literature review identified 12 cases of inhibitors in pediatric patients after thrombin exposure.[93] In eight cases the antibodies were directed against human coagulation proteins; five of these patients had hemorrhagic complications. Bleeding manifestations included cutaneous, gastrointestinal, pulmonary, and cerebral hemorrhages. Patients exhibited both PT and aPTT prolongations and mixing studies consistent with an inhibitor. Specific factor activity assays revealed the target for the inhibitor. However, there was no correlation between laboratory studies and clinical bleeding. Corticosteroids and γ-globulin have been used with resolution of the inhibitor over days to weeks. Platelet transfusions are another option, insofar as approximately 20% of factor V activity is present in platelet granules that are shielded from circulating antibodies.[94] Coagulation factor inhibitors should be suspected in any postoperative patient exposed to topical bovine thrombin presenting with a prolonged PT and aPTT.

Acquired Inhibitors to Other Coagulation Factors

Antifibrinogen antibodies are extremely rare and may or may not be associated with clinical bleeding. An increased rate of fibrinogen antibodies has been described in pregnant and peripartum women.[95] Acquired inhibitors directed against coagulation factors VII and X have been observed with malignancies, autoimmune disorders, and drug exposure. In addition, acquired inhibitors against factor XI have been rarely reported, including in patients with underlying SLE.[96]

Acquired von Willebrand Syndrome

Acquired von Willebrand syndrome (AVWS) is a rare bleeding disorder with clinical and laboratory findings similar to those in inheritedVWD. Since its original description in 1968 in a patient with systemic lupus erythematosus, fewer than 700 cases have been reported.[97] AVWS usually occurs in individuals with no personal or family history of VWD and is accompanied by bleeding symptoms in about three quarters of patients, whereas others are diagnosed on the basis of abnormalities found during routine hemostasis screening tests.[98] As would be expected, mucocutaneous bleeding symptoms predominate. Underlying disorders are identified frequently and fall into the following main categories: lymphoproliferative and myeloproliferative disorders; solid tumors; immunologic and cardiovascular disorders; and other miscellaneous conditions, including drug associations. It is typically a syndrome of advanced age, although it has also been reported in children, and is primarily associated with congenital heart disease, collagen vascular diseases, Wilms tumor, hypothyroidism, and use of certain drugs. Drug-associated AVWS has been described in up to 20% of pediatric patients who received valproic acid, although bleeding manifestations were mild and did not require discontinuation of the anticonvulsant.[99]

Four main pathogenic mechanisms can lead to AVWS: (1) reduced VWF synthesis (as seen in severe hypothyroidism or certain drugs (e.g., valproic acid); (2) inhibition or clearance by paraproteins or autoimmune inhibitors (this has been observed in association with B-cell lymphomas, monoclonal gammopathies, multiple myeloma, and autoimmune disorders); (3) absorption of VWF high-molecular-weight multimers onto malignant cell clones or platelets; (4) increased shear stress and proteolysis, as may occur with aortic stenosis, artificial heart valves, left ventricular assist devices, or other cardiac defects with disturbed flow.[97] Laboratory studies rely on detecting abnormally reduced functional VWF studies (ristocetin cofactor activity, collagen-binding assay) in comparison to VWF antigen and a selective deficiency of the high-molecular-weight multimers. A search for evidence of an inhibitor should be performed by measuring VWF activity after mixing experiments involving patient plasma and normal plasma incubated at 37° C.

The three goals of treatment should be control of active bleeding, prevention of bleeding with necessary invasive procedures, and treatment of the underlying disease. Desmopressin and factor VIII/VWF concentrates have provided only short-term control of bleeding in the presence of autoantibodies.[100] In those cases γ-globulin, corticosteroids, or other immunosuppressive agents have been administered. Recombinant VIIa may also be effective with this presentation.[101] In noninhibitor-associated AVWS, factor VIII/VWF concentrates are effective in most patients, although the half-life may be shorter.[97] Desmopressin may be used to control bleeding, although there is a relatively lower rate of success among patients with cardiovascular or myeloproliferative disorders.[102] Ultimately, normalization of hemostasis may not be seen until the underlying precipitating condition is treated effectively (e.g., with surgery or chemotherapy for Wilms tumor).

Acquired Inhibitors to Prothrombin—Hemorrhagic Lupus Anticoagulant Syndrome

LA represent a diverse group of antibodies directed against proteins bound to phospholipids. They may be found in patients with systemic lupus erythematosus and other autoimmune disorders but also in otherwise healthy individuals and have been implicated in thrombotic complications. However, in children they are most often identified after investigation of a prolonged aPTT seen as part of pre-surgical evaluation or associated with a history of infection.[103] In the vast majority of these cases, they are asymptomatic (including no bleeding manifestations), transient, usually resolving over days to weeks, and do not preclude proceeding with invasive procedures. However, a rare hemorrhagic LA syndrome (ecchymoses, epistaxis, gastrointestinal bleeding, hematomas and even hemarthroses) has been observed with associated low prothrombin levels.[104-109] This would be manifest by a concurrent prolongation of the PT (unusual for an uncomplicated LA) and pathogenically is believed to be caused by antiprothrombin antibodies. These are not typically neutralizing and, as a result, mixing studies may not indicate the presence of an inhibitor. Rather, the formation of immune complexes leads to increased plasma clearance.[110] Antibodies have been characterized directed against the carboxy terminal portion of the prothrombin molecule.[111] Bleeding symptoms usually resolve without therapy, although patients with significant bleeding symptoms may be treated with prothrombin complex concentrates. Corticosteroids and other immune suppressants have been used in some cases.

ACQUIRED THROMBOEMBOLIC DISEASE

Thromboembolism (TE) in children has become increasingly diagnosed in recent years thanks to enhanced survival rates associated with serious underlying illnesses, heightened use of invasive vascular procedures and devices, and a growing (albeit still suboptimal) awareness that TE does indeed occur in children. The subsequent portion of this chapter summarizes the clinical spectrum and characterization of pediatric TE, key considerations for diagnostic evaluation and antithrombotic management, and long-term outcomes. Emphasis is also placed on unresolved and emerging clinical and investigative issues in the field.

Characterization of Thromboembolism in Children

TE is anatomically classified by vascular type (i.e., venous versus arterial), distribution (e.g., distal lower extremity versus proximal lower extremity versus central; superficial versus deep vasculature), and organ system affected, if applicable (e.g., renal vein thrombosis, cerebral sinovenous thrombosis, pulmonary embolism [PE]). TE is also distinguished by the additional clinically relevant factors of first episode versus recurrent, symptomatic versus asymptomatic, acute versus chronic (a sometimes-difficult distinction), veno-occlusive versus nonocclusive, and idiopathic versus risk associated. This last category includes both clinical prothrombotic risk factors (e.g., exogenous estrogen administration, indwelling central venous catheter, reduced mobility) and blood-based thrombophilic conditions (e.g., transient or persistent antiphospholipid antibodies, acquired or congenital anticoagulant deficiencies, the factor V Leiden or prothrombin 20210 mutations), as discussed in greater detail later in the section "Etiology." In light of the frequency of indwelling central venous catheters as a clinical risk factor for TE in children, provoked TE is often also classified as catheter related versus non–catheter related.

Venous Thromboembolism

Epidemiology

Several national or international registries in the past two decades have evaluated the occurrence of venous thromboembolism (VTE) in children. From these data a cumulative incidence of 0.07 per 10,000 (5.3 per 10,000 hospitalizations) was estimated for extremity deep venous thrombosis (DVT) and PE among non-neonatal Canadian children,[112] and an incidence rate of 0.14 per 10,000 children per year was reported for all VTE in the Netherlands.[113] In 2004 evaluation of the National Hospital Discharge Survey and census data for all VTE in the United States disclosed an overall incidence rate of 0.49 per 10,000 per year.[114] More recently, an analysis of the Pediatric Health Information System database revealed a nearly 70% increase in the diagnosis of VTE among hospitalized children, as defined by International Classification of Disease-9 diagnostic codes, over a 7-year period from 2001 to 2007.[115]

Closer examination of epidemiologic data reveals that the age distribution of the incidence rate for VTE in children is bimodal, with peak rates in the neonatal period and adolescence. With regard to the newborn period, the cumulative incidence of venous or arterial TE was reported to be 0.51 per 10,000 births in Germany[116] and 24 per 10,000 admissions to neonatal intensive care units in Southern Ontario.[117] The Dutch registry indicated a VTE-specific incidence rate of 14.5 per 10,000 per year in the neonatal period, approximately 100 times greater than the overall rate in childhood.[113] Among adolescents 15 to 17 years of age, the VTE-specific incidence rate in the United States was determined to be 1.1 per 10,000 per year, a rate nearly threefold that observed overall in childhood.[114]

Although differing selection criteria have contributed to the considerable variability in occurrence estimates in the preceding example, it is clear that the incidence of VTE in children is lower than that among middle-aged and elderly adults. Nevertheless, as discussed later in this chapter, the sequelae of VTE in children, particularly with regard to the post-thrombotic syndrome (PTS), appear to be at least as frequent and severe as those among adults.

Etiology

The pathogenesis of VTE can be readily appreciated by considering Virchow's triad, consisting of venous stasis, endothelial damage, and the hypercoagulable state. In children, greater than 90% of VTE are risk-associated[113,118,119] (compared with approximately 60% in adults), with risk factors often disclosed from more than one component of this triad. Specific examples of VTE risk factors in children are shown in Figure 35-1. Among the most common of clinical prothrombotic risk factors in childhood is an indwelling central venous catheter. Over 50% of cases of DVT in children and over 80% of cases in newborns occur in association with central venous catheters.[112,117] The reported cumulative incidence or prevalence of catheter-related thrombosis (CRT) in children receiving home TPN ranges widely, from 1% to 80%[120-125]; this broad variation is largely influenced by differing study designs, selection criteria, and diagnostic imaging modalities. The presence of an indwelling central venous catheter, the underlying malignancy or disorder for which bone marrow transplantation was undertaken, and congenital cardiac disease and its corrective surgery were all highly prevalent in the Canadian pediatric thrombosis registry,[119] whereas underlying infectious illness and the presence of an indwelling central venous catheter were identified as pervasive clinical risk factors in a recent cohort study analysis from the United States.[118] It is likely that differences in the composition of referral populations strongly contribute to differences in the composition of VTE etiologies across major pediatric thrombosis centers.

With regard to blood-based risk factors for VTE, thrombophilic conditions (e.g., severe anticoagulant deficiencies , antiphospholipid antibodies [APAs]) in children are frequently acquired, and severe inherited thrombophilias are rare. By contrast, mild congenital thrombophilic traits (e.g., the factor V Leiden and prothrombin 20210 mutations) are common in Caucasian children, as in adults (see Chapter 33). Thrombophilia is potentially caused by any alteration in hemostatic balance that increases thrombin production, enhances platelet activation or aggregation, mediates endothelial activation or damage, or inhibits fibrinolysis. Common examples of acquired thrombophilia in children include increased factor VIII activity with significant infection and inflammatory states, anticoagulant deficiencies resulting from consumption in bacterial sepsis and DIC, the production

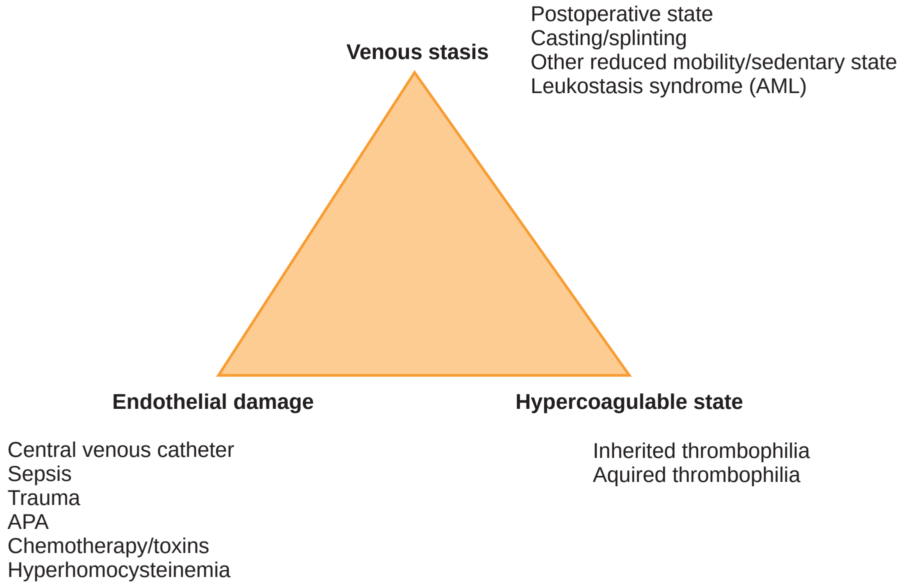

Figure 35-1 Clinical prothrombotic risk factors: Virchow's triad applied to venous thromboembolism in children.

of inhibitory antibodies in acute viral infection, and parainfectious development of APA. To provide an appreciation of the magnitude of VTE risk increase associated with several congenital or genetically influenced thrombophilia traits, population-based VTE risk estimates derived from the adult literature are shown in Table 35-1. For example, the addition of standard-dose estrogen oral contraceptive pill to underlying heterozygous factor V Leiden substantially increases the risk for VTE from a baseline risk of 15 per 10,000 U.S. females aged 15 to 17 years per year[114] to a risk of more than 500 per 10,000 (or 5%) per year.

Clinical Presentation

The degree of clinical suspicion for acute VTE in children should be principally influenced by clinical prothrombotic risk factors and family history of early VTE or other vascular disease elicited on thorough interview, known thrombophilia traits and risk factors, and clinical signs and symptoms. The signs and symptoms of VTE depend on anatomic location and organ systems affected and are influenced by characteristics of veno-occlusiveness and chronicity. The classic manifestation of acute extremity DVT is painful unilateral limb swelling. The lack of other physical examination findings (e.g., Homans sign, the presence of a palpable cord in the popliteal fossa in the clinical evaluation for lower extremity DVT) should not reduce the clinical index of suspicion of DVT. In upper extremity DVT with extension into, and occlusion of, the superior vena cava (SVC), signs and symptoms may include swelling of the neck and face, bilateral periorbital edema, and headache. PE is classically manifested by sudden-onset, unexplained shortness of breath with pleuritic chest pain. When PE is proximal or extensive bilaterally in the distal pulmonary arterial tree, hypoxemia is often demonstrated. Associated right-sided heart failure may manifest with hepatomegaly and peripheral edema. Proximal PE and especially saddle embolus can present with cyanosis or sudden collapse. However, in many cases PE may be asymptomatic or produce only subtle symptoms in children,[126-129] especially when involving limited segmental branches of the pulmonary arteries and not eliciting a significant pleural reaction. In one retrospective series 14% of affected children had no clinical symptoms attributable to PE.[127] Acute cerebral sinovenous thrombosis (CSVT) may present with unusually severe and persistent headache, blurred vision, neurologic signs (e.g., cranial nerve palsy, papilledema), or seizures. The classic findings in renal vein thrombosis (RVT) are hematuria and thrombocytopenia, sometimes associated with uremia (especially when bilateral). Presenting signs include oliguria (especially when bilateral), and in the neonatal period (the time at which RVT is most common during childhood) a flank mass is often palpable on examination.[130] RVT in older children is often associated with nephrotic syndrome (a risk factor for VTE in general owing to the loss of anticoagulant proteins) and hence may present with associated stigmata of peripheral and periorbital edema when diagnosed at presentation of nephrosis.[128] Thrombocytopenia may be a presenting manifestation

TABLE 35-1 Venous Thromboembolism Risk Estimates for Selected Thrombophilia Traits and Conditions

Trait/Condition	VTE Risk Estimate
Hyperhomocysteinemia	2.5×
Prothrombin 20210 mutation, heterozygous	3×
OCP (standard dose estrogen)	4×
Factor V Leiden mutation, heterozygous	2-7×
Factor V Leiden mutation, heterozygous, + OCP	35×
Factor V Leiden mutation, homozygous	80×

OCP, Oral contraceptive pill; *VTE,* venous thromboembolism.

not only of RVT but also of intracardiac (e.g., right atrial) thrombosis, especially as a CRT associated with sepsis.[131] Isolated intracardiac thrombosis in association with cardiac surgery or central venous catheter placement is most often asymptomatic.[132] Portal vein thrombosis is one of the most common causes of portal hypertension in children, characteristically presenting with splenomegaly, and is associated with findings of hypersplenism (anemia, neutropenia, and thrombocytopenia); gastrointestinal bleeding at presentation typically signals the presence of gastroesophageal varices.[133,134] Internal jugular vein thrombosis may manifest with neck pain or swelling, and when part of Lemierre syndrome is classically also associated with fever, trismus, pain on lateral neck rotation, and a palpable mass in the lateral triangle of the neck.[135]

Chronic VTE may be diagnosed incidentally without signs or symptoms (as sometimes occurs for CSVT during unrelated brain imaging), or it may present with signs and symptoms of chronic venous obstruction or PTS, including pain and edema of dependent extremities, dilated superficial collateral veins, venous stasis dermatitis, and frank ulceration of the skin.

Diagnosis

Whereas venography has historically been the gold standard for diagnosis of venous thrombosis, this modality is invasive and has become less prevalent in recent years with the development of effective noninvasive or minimally invasive radiologic imaging technologies. Radiologic imaging is used not only to confirm the clinical diagnosis of VTE but also to define both the extent and occlusiveness of thrombosis. For suspected DVT of the distal or proximal lower extremity, compression ultrasound with Doppler is typically employed for objective confirmation. When the thrombus may affect or extend into deep pelvic or abdominal veins, computed tomography (CT) is often necessary. For circumstances in which radiation exposure is a significant concern or alternative diagnoses (e.g., myositis) are being evaluated, magnetic resonance imaging (MRI) may alternatively be employed. Magnetic resonance venography may be useful in documenting May-Thurner syndrome, an uncommon cause of all lower extremity DVT (but seemingly a common cause of spontaneous or minimally provoked left-sided iliofemoral DVT) in which the iliac vein is compressed by an overriding right common iliac artery.[136] In suspected DVT of the upper extremity, compression ultrasound with Doppler effectively evaluates the limb, but echocardiography or CT is required to disclose involvement of more central vasculature (e.g., right atrial thrombosis). In the case of asymptomatic nonocclusive extremity DVT, venography may be used as an alternative to CT. It is important to recognize that venography (in which radiographic contrast is administered into a vein in the limb) should not be confused with "line-o-grams" (in which radiographic contrast is instilled into a central venous catheter). The latter studies are useful for delineating catheter tip thrombi but cannot reliably detect DVT along the intravascular length of a central venous catheter.[137] Magnetic resonance venography has replaced conventional venography in most centers. However, dynamic conventional venography may be required to evaluate for thoracic outlet syndrome (mechanical compression and entrapment of the subclavian vessels in the region of the thoracic outlet, whether owing to a congenitally narrow subclavian passage between the clavicle, first rib, and a hypertrophied subclavius muscle in athletes [Paget-Schroetter syndrome] or to an accessory rib).[138] To establish a diagnosis of DVT of the jugular venous system, compression ultrasound with Doppler is typically sufficient.

PE in children is commonly diagnosed by spiral CT or, alternatively, by ventilation-perfusion scan, the latter generally being suboptimal in cases wherein other lung pathology exists and at centers wherein availability of, and expertise with, this modality are limited. CSVT is typically diagnosed by standard CT or CT venography, and alternatively by MRI or magnetic resonance venography. The diagnosis of RVT is most often made clinically in neonates and is supported by Doppler ultrasound findings of intrarenal vascular resistive indices; however, in some cases a discrete thrombus may be suggested by Doppler ultrasound, especially when extending into the inferior vena cava. When RVT occurs in older children, Doppler ultrasound or CT is often diagnostic. Similarly, portal vein thrombosis is typically visualized by Doppler ultrasound or CT.

When new-onset venous thrombosis is being evaluated in patients in areas of anatomic abnormality of the venous system (e.g., extensive collateral venous circulation caused by a prior VTE episode, May-Thurner anomaly, atretic inferior vena cava with azygous continuation), more sensitive methods such as CT or magnetic resonance venography are often required to adequately delineate the vascular anatomy as well as the presence, extent, and occlusiveness of thrombosis.

Diagnostic laboratory evaluation for pediatric acute VTE includes a complete blood count, evaluation for thrombophilia (see "Etiology"), and beta-human chorionic gonadotropin in postmenarchal women. Additional laboratory studies may be warranted depending on associated medical conditions and VTE involvement of specific organ systems.

Treatment

A summary of conventional antithrombotic agents and corresponding target anticoagulant levels, based on recent pediatric recommendations,[139] is provided in Table 35-2 for both initial (i.e., acute phase) and "extended" (i.e., subacute phase) treatment. Conventional anticoagulants attenuate hypercoagulability, decreasing the risk of thrombus progression and embolism, and rely on intrinsic fibrinolytic mechanisms to break up the thrombus over time. The most commonly employed conventional anticoagulants in children include heparins and warfarin. Heparins, including unfractionated heparin and low-molecular-weight heparin (LMWH), enhance the activity of AT, an intrinsic anticoagulant that serves as a key inhibitor of thrombin. Warfarin acts through antagonism of VK, thereby interfering with γ-carboxylation of the VK-dependent procoagulant factors II, VII, IX, and X.

TABLE 35-2 Recommended Intensities and Durations of Conventional Antithrombotic Therapies in Children, by Etiology and Treatment Agent

	Agents and Target Anticoagulant Activities		
Episode	Initial Treatment	Extended Treatment	**Duration of Therapy, by Etiology**
First	UFH 0.3-0.7 anti-Xa U/mL LMWH 0.5-1.0 anti-Xa U/mL	Warfarin INR 2.0-3.0 LMWH 0.5-1.0 anti-Xa U/mL	Resolved risk factor: 3 months No known clinical risk factor: 6-12 months Chronic clinical risk factor: 12 months Potent congenital thrombophilia: indefinite
Recurrent	UFH 0.3-0.7 anti-Xa U/mL LMWH 0.5-1.0 anti-Xa U/mL	Warfarin INR 2.0-3.0 LMWH 0.5-1.0 anti-Xa U/mL	Resolved risk factor: 6-12 months No known clinical risk factor: 12 months Chronic clinical risk factor: indefinite Potent congenital thrombophilia: indefinite

INR, International normalized ratio; *LMWH,* low-molecular-weight heparin; *UFH,* unfractionated heparin.

Initial Anticoagulation. Initial anticoagulant therapy (i.e., acute phase) for VTE in children generally uses unfractionated or LMWH. LMWH has become increasingly employed as a first-line agent for initial anticoagulant therapy in children, given the relative ease of subcutaneous over intravenous administration, the decreased need for blood monitoring of anticoagulant efficacy, and a decreased risk of the development of heparin-induced thrombocytopenia (HIT). Unfractionated heparin is typically preferred in circumstances of heightened bleeding risk or labile acute clinical status, given the rapid extinction of anticoagulant effect following cessation of the drug. In addition, unfractionated heparin is used for acute VTE therapy in renal insufficiency, given the renal excretion of LMWH. Common initial maintenance dosing for unfractionated heparin in nonneonatal children ranges from 15 to 25 U/kg/h preceded by a loading dose of 50 to 75 U/kg. In full-term neonates a maintenance dose of up to 50 U/kg/h may be required, especially if the clinical condition is complicated by AT consumption. The starting dose for the LMWH enoxaparin in nonneonatal children commonly ranges between 1 and 1.25 mg/kg; no bolus dose is given. In full-term neonates an enoxaparin starting dose of 1.5 mg/kg is typically necessary.[140] For the LMWH dalteparin, initial maintenance dosing of 100 to 150 anti–factor Xa U/kg) appears appropriate based on available pediatric data.[141] Heparin therapy is monitored most accurately by anti–factor Xa activity. For unfractionated heparin the therapeutic range is 0.3 to 0.7 anti–factor Xa activity U/mL, whereas for LMWH the therapeutic range is 0.5 to 1 U/mL. When anti–factor Xa assay is not available, the activated partial thromboplastin time (aPTT) may be used, but it is suboptimal in the pediatric age group, in which antiphospholipid antibodies may interfere with or artifactually prolong the clotting endpoint; indeed, one study of pediatric heparin monitoring demonstrated inaccuracy of aPTT approximately 30% of the time.[142] When dosed by weight in childhood, LMWH does not require frequent monitoring, but anti–factor Xa activity should be evaluated with changes in renal function. In addition, in cases of acute VTE in which acquired AT deficiency is related to consumption in acute infection or inflammation, anti–factor Xa activity may rise as AT levels normalize with resolution of the acute illness; in this circumstance follow-up evaluation of anti–factor Xa activity is warranted in the subacute period. The recommended duration of initial heparin therapy for acute VTE, 5 to 10 days, has been extrapolated from adult data.[143] Unfractionated heparin treatment is rarely maintained beyond the acute period, given the risk of osteoporosis with extended administration[139] and the inconvenience of continuous intravenous administration. Although adult data suggest efficacy of subcutaneous administration of unfractionated heparin for acute VTE,[144] this has been evaluated only for the acute therapy period before extended therapy with warfarin, and the appropriateness of such an approach in children has not been established.

Extended Anticoagulation. "Extended" anticoagulant therapy (i.e., subacute phase) for VTE in children may employ LMWH or warfarin. Warfarin may be started during the acute phase; however, because severe congenital deficiencies involving the protein C pathway can present as VTE in early childhood and are associated with warfarin skin necrosis,[145] warfarinization should ideally be initiated only after therapeutic anticoagulation is achieved with heparin-based treatment. Warfarin is monitored by INR, derived from the measured PT. The therapeutic INR range for warfarin anticoagulation in VTE is 2 to 3.[139] Historical evidence for maintaining a higher INR (2.5 to 3.5) in the presence of APA is not supported by data from more recent studies[146,147]; however, maintaining an INR of 2.5 to 3, when feasible, satisfies both older and more recent literature criteria with regard to appropriate safety and efficacy in this subset of patients.

Duration of Therapy. Pediatric recommendations for the duration of antithrombotic therapy in acute VTE[139] are largely derived from evidence from adult trials. For a provoked first episode of VTE in children, the recommended duration of anticoagulant therapy is 3 months, as long as the provoking risk factor does not persist beyond 3 months (e.g., postoperative VTE), and—in the authors' view—absent a potent chronic thrombophilia state (e.g., APA syndrome, homozygous anticoagulant deficiency). The recommended duration is 6 to 12 months when spontaneous and 12 months to lifelong when a chronic risk factor persists (e.g., systemic lupus erythematosus). Recurrent VTE is treated for 6 to 12 months in the presence of an underlying reversible risk factor, 12 months to lifelong when spontaneous, and lifelong when a chronic risk factor persists. Children with SLE and persistence of an LA have a 16- to 25-fold greater risk of TEs than children with SLE and no LA.[148] However, in children with primary (i.e., idiopathic) or secondary (i.e., associated with SLE or other underlying chronic inflammatory condition) VTE, it is possible that the autoimmune disease will become quiescent in later years, such that the benefit of continued VTE prophylaxis may be reevaluated. Some experts have recommended consideration of low-dose anticoagulation as secondary VTE prophylaxis after a conventional 3- to 6-month course of therapeutic anticoagulation for VTE in children with SLE who have APA syndrome.[149] However, further study to optimize the intensity and duration of therapy or secondary prophylaxis for VTE in children with APA syndrome is urgently needed, especially in light of evidence in adult provoked VTE that secondary prophylaxis with low-dose warfarin not only may offer little risk reduction beyond no anticoagulation but also is associated with bleeding complications despite a reduced warfarin dose.[150,151]

Thrombolytics. Whereas the aforementioned anticoagulant therapies are conventional in pediatric acute VTE, thrombolytic approaches are gaining increased attention and use during acute VTE therapy in children with hemodynamically significant PE or extensive limb-threatening VTE. Unlike conventional anticoagulants, thrombolytics directly promote fibrinolysis. Tissue-type plasminogen activator is an intrinsic activator of the fibrinolytic system and has been administered exogenously as a systemic bolus or short-duration infusion, a systemic low-dose continuous infusion, or a local catheter-directed infusion with or without interventional mechanical thrombectomy or thrombolysis. A few small cohort study analyses of children with acute proximal limb DVT who had an a priori high risk of poor post-thrombotic syndrome by virtue of completely veno-occlusive thrombus with plasma FVIII activity greater than 150 U/dL or D-dimer concentration greater than 500 ng/mL have revealed that a thrombolytic regimen followed by standard anticoagulation offers potential reduction in the risk of post-thrombotic syndrome when compared (either concomitantly or historically) to standard anticoagulation alone.[152,153] A National Institutes of Health–sponsored planning grant was begun in 2012 for a future randomized controlled trial on the efficacy and safety of thrombolysis versus standard anticoagulation for acute completely occlusive proximal lower-extremity DVT in children (Goldenberg and Manco-Johnson, personal communication).

Other Anticoagulants. Other antithrombotic agents include fondaparinux, intravenous and oral direct thrombin inhibitors, and oral direct factor Xa inhibitors. Fondaparinux is a parenteral selective factor Xa inhibitor. It is a synthetic pentasaccharide that rapidly binds to AT in the blood, potentiating the natural inhibitory effect of AT against factor Xa, thus indirectly inhibiting thrombin. Fondaparinux is typically administered once daily as a subcutaneous injection. Dosing in children has been informed by a pediatric pharmokinetic and safety study.[154] Direct thrombin inhibitors, by contrast, inhibit thrombin directly by binding to exosite I or the active site of thrombin (or both).[155] These drugs include hirudin and recombinant hirudins such as lepirudin. Argatroban is a synthetic small molecule derived from L-arginine and functions as a reversible direct thrombin inhibitor. Intravenous direct thrombin inhibitors are routinely monitored by aPTT, with the therapeutic goal ranging from a 1.5- to 3.0-fold aPTT prolongation. At present, intravenous direct thrombin inhibitors are indicated for the treatment of HIT, particularly when associated with acute thrombosis (HITT). Indeed, this is the setting in which pharmacokinetic studies of argatroban have been conducted.[156] However, pediatric use of intravenous direct thrombin inhibitors has also been reported in settings of catastrophic APA syndrome and thrombotic storm.[157]

Oral direct thrombin inhibitors and oral direct factor Xa inhibitors have been developed as a possible alternative to warfarin. They have the advantage of oral bioavailability, low intersubject variation, no metabolism by the hepatic cytochrome P450 system, a low incidence of drug-drug interactions, and no dietary influence. Early-phase pediatric clinical trials in pediatric VTE prevention or treatment with the oral direct thrombin inhibitor dabigatran and the oral direct factor Xa inhibitors apixaban and rivaroxaban were all initiated between 2011 and 2012, after regulatory agency approvals for the corresponding adult indications.[158]

Other Therapeutic Agents. Other products may have antithrombotic roles in selected circumstances but lack definitive demonstration of efficacy and safety in clinical trials. For example, plasma replacement with protein C concentrate is a useful adjunctive therapy for VTE or purpura fulminans owing to microvascular thrombosis in severe congenital protein C deficiency[159-161] and may play a beneficial role in the treatment of purpura fulminans owing to microvascular thrombosis in children with sepsis, particularly in meningococcemia.[162-164] In addition, case series have suggested a role for AT replacement in prevention of VTE in children and young adults with congenital severe AT deficiency,[165] for the prevention of L-asparaginase–associated VTE in pediatric acute lymphoblastic leukemia (ALL),[166,167] and as combination therapy with defibrotide in the prevention and treatment of hepatic sinusoidal obstruction syndrome (formerly termed *veno-occlusive disease*) in children undergoing hematopoietic stem cell transplanation.[168] The potential benefit toward VTE risk reduction of a regimen of AT replacement combined with daily prophylactic LMWH during induction and consolidation phases of therapy in ALL has also been suggested by a historically controlled cohort study of the BFM 2000 protocol experience in Europe.[169] AT replacement may also be worthy of consideration in patients with acute VTE undergoing heparinization in whom significant AT deficiency prevents the achievement of therapeutic anti–factor Xa levels (i.e., heparin "resistance"). This may be seen in neonates with clinical conditions complicated by AT consumption superimposed on the physiologic relative deficiency of this key intrinsic thrombin inhibitor in the newborn period. However, AT replacement in preterm neonates has been investigated to improve the outcomes of respiratory distress syndrome, intracranial hemorrhage, and sepsis but has failed to demonstrate benefit and may contribute to adverse events.[170]

Vena Cava Filters. In certain circumstances vena cava filters may serve an adjunctive role in antithrombotic management in children. The use of vena cava filters should be considered in children of appropriate size in whom contraindications to anticoagulation exist or in whom recurrent VTE (especially PE) has occurred despite therapeutic anticoagulation and in the absence of a reversible risk factor. In addition, "temporary" or retrievable vena cava filters may be considered during times of especially heightened risk for PE or at times when therapeutic anticoagulation is transiently considered to engender a heightened risk of hemorrhagic complications (e.g., recent neurosurgery). The presence of the filter alone is not an indication for long-term anticoagulation because the risk for vena caval thrombosis related to the device is low. Long-term outcomes in adult series have shown a failure rate (clinically relevant, symptomatic PE) of 3.3% to 5.6%.[171-173] Major complications were infrequent (<1%) and include rare cases of caudal migration, filter fractures, or caval wall perforation.[173] A retrospective review of 15 children 18 years of age or younger suggested efficacy of long-standing vena cava filters with regard to primary and secondary prevention of PE.[174] Follow-up was a mean of 9.2 years (range 19 months to 16 years), and there were no significant complications, complementing similar findings in other small case series.[175,176] However, until the impact of such nonretrievable devices on the vena cava of the developing child has been better studied, their use in preadolescents should be undertaken with caution. Experience with surgical removal of retrievable vena cava filters is quite limited in children with unknown risks and costs of extraction. Surgical removal of permanent vena cava filters should be strongly discouraged because this often requires vena caval ligation.[177]

Outcomes

Complications of VTEs can occur both acutely and over the long term and are germane to both CRT and non-CRT. Short-term adverse outcomes include major hemorrhagic complications of antithrombotic interventions, as well as of the thrombotic event itself (e.g., post-thrombotic hemorrhage in the brain or adrenal gland); thrombus progression (involvement of previously unaffected contiguous venous segments, or change from nonocclusive to occlusive); early recurrent VTE (including DVT and PE[178]); SVC syndrome in DVT of the upper venous system[178,179]; acute renal insufficiency in RVT[180]; catheter-related sepsis,[181] PE,[182,183] and catheter malfunction (sometimes necessitating surgical replacement) in CRT; severe acute venous insufficiency leading to venous infarction with limb gangrene in rare cases of occlusive DVT involving the extremities; and death from hemodynamic instability in extensive intracardiac thrombosis or proximal PE.[112] Long-term adverse outcomes in pediatric VTE have been previously reviewed[184] and include recurrent VTE; chronic hypertension and renal insufficiency in RVT; variceal hemorrhage in portal vein thrombosis[112]; chronic SVC syndrome in CRT involving SVC occlusion; loss of availability for venous access in recurrent or extensive CRT of the upper venous system; and development of PTS, a condition of chronic venous insufficiency following DVT. The manifestations of PTS include (in order of increasing severity) edema, visibly dilated superficial collateral veins, venous stasis dermatitis, and venous stasis ulcers (Fig. 35-2). Given the long-term and sometimes lifelong risks of disease sequelae as in RVT and functional impairment as in PTS, venous thrombosis is best considered a chronic disorder in children.

Long-Term Outcomes. The long-term outcomes of VTE in children, specifically with regard to recurrent VTE, PTS, major hemorrhage, and death, are summarized in Table 35-3. Registry[112,119,185] and cohort study[118] data in pediatric VTE of all types indicate that children appear

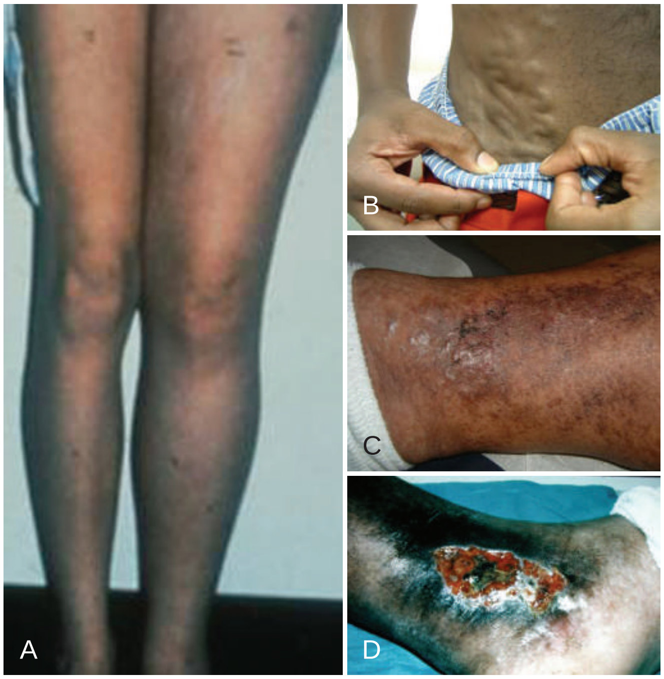

Figure 35-2 Manifestations of post-thrombotic syndrome in children. **A,** Stage 1: chronic edema with iliofemoral deep venous thrombosis *(DVT)* at 16 years of age. The patient was heterozygous for factor V Leiden and was taking oral contraceptive pills. **B,** Stage 2: dilated superficial venous collateral circulatioin in a 14-year-old adolescent with inferior vena cava *(IVC)* DVT as a result of antiphospolipid antibody *(APA)* and prolonged travel. **C,** Stage 3: chronic venous stasis dermatitis in a 13-year-old with IVC DVT who was heterozygous for factor V Leiden and exhibited APA. **D,** Stage 4: chronic ulceration in a 10-year-old with femoral popliteal DVT, homozygous protein C deficiency, and a tibial fracture.

TABLE 35-3 Outcomes of Venous Thromboembolism in Children

Author	Year of Publication	Country	# VTE Cases	Mean/Median Duration of Follow-up	Major Bleeding	Recurrent VTE	PTS	VTE-Related Mortality
Monagle et al.[119]	2000	Canada	405	3 years	N/A	8%	12%	2%
Nowak-Göttl et al.[188]	2001	Germany	301	7 years	N/A	21%	N/A	0%

to have a lower risk of recurrent TE than adults (cumulative incidences at 1 to 2 years of 6% to 11% versus 12% to 22%,[186,187] respectively). However, the risk of PTS in children with DVT of the limbs appears to be at least as great as that in adults (cumulative incidences at 1 to 2 years of 33% to 70%[113,118] versus 29%, respectively[187]). In addition, in a German cohort study of children with spontaneous VTE[188] (i.e., VTE in the absence of identified clinical risk factors), the cumulative incidence of VTE at a median follow-up time of 7 years was 21%, suggesting that, in this subgroup of pediatric VTE, the risk for recurrent VTE is long-lived. Although VTE-specific mortality in children is quite low, ranging from 0% to 2% in these and other[189,190] studies, a considerably higher all-cause mortality indicates the severity of underlying conditions (e.g., sepsis, cancer, congenital cardiac disease) in pediatric VTE. Neonate-specific outcome data in pediatric non-RVT VTE reflect an all-cause mortality of 12% to 18%,[116,117,191] including one series of premature infants with CRT treated with enoxaparin.[191] Bleeding (including all severities) occurs in approximately 20% of children treated with a therapeutic course of oral VK antagonists and 17% receiving LMWH; so-called "major" hemorrhage occurs in 2% to 4%.[192]

Outcomes by Anatomic Site. Outcomes of VTE in children may differ among specific anatomic sites and organ systems affected, as well as in relation to the presence or absence of a central venous catheter. Analyses devoted specifically to CRT in children are limited; however, given the high prevalence of CRT in registries and cohort studies of pediatric VTE, outcomes of CRT are likely to considerably influence the data discussed previously for VTE in general. In a Canadian study of CRT in children from 1990 to 1996,[183] VTE-specific mortality was 4%—and 20% among PE cases. No major bleeding episodes were observed. At a median follow-up duration of 2 years, the cumulative incidence of symptomatic recurrent VTE was 6.5%, and PTS developed in 9% of children. In published series of RVT[130,180,193-195] (primarily among neonates), VTE-related death has been very rare, and the cumulative incidence of recurrent VTE has ranged from 0% to 4%, albeit with wide variation in duration of follow-up across studies. The cumulative incidence of chronic hypertension in RVT in these studies was reported at 22% to 33%. The pediatric literature devoted to CSVT[196,197,198,199] is somewhat smaller than that for RVT and suggests a broad range of VTE-specific mortality of 4% to 20%, with a cumulative incidence of recurrent VTE of 8% for neonatal CSVT cases and 17% for CSVT occurring in older children.[198] Long-term neurologic sequelae were noted in 17% to 26% of CSVT cases diagnosed in the neonatal period and 8% to 47% of those occurring later in childhood. It is worth noting that in the aforementioned pediatric series of RVT and CSVT, both the proportion of children who received anticoagulation and the duration of the anticoagulation course varied considerably across studies. Few pediatric series reporting outcomes of portal vein thrombosis have been published; however, it appears that the risk of developing recurrent gastrovariceal bleeding in this population is substantial, often despite surgical interventions to reduce portal hypertension.[200] With regard to long-term outcomes of PE in childhood, in a recent single-institutional cohort study[201] of 58 patients with acute PE treated with conventional anticoagulation (nearly half of whom had hypoxemia at presentation, and in which signs of right ventricular dysfunction of triscuspid regurgitant velocity >3 m/s, septal flattening, and right ventricular dilation were each present acutely on echocardiogram in 25%), there were no PE-related deaths and the cumulative incidence of recurrent VTE in long-term follow-up was 9%. The prevalence of persistent PE at 6 months follow-up was 18%, and on follow-up echocardiogram at a median time of approximately 1.5 years, signs of right ventricular dysfunction of triscupid regurgitant velocity greater than 3 m/s, septal flattening, and right ventricular dilation were observed in 0%, 13%, and 13%, respectively. It is noteworthy that 26% of the cohort had received acute thrombolytic therapy with tPA.

An additional outcome of interest to patients and families of children with VTE is persistence versus resolution of thrombosis. Data to date, largely from adult VTE populations, suggest that the persistence of thrombosis after a therapeutic course of anticoagulation of appropriate duration does not appreciably increase the risk for recurrent VTE, including PE. However, some evidence[202] indicates that persistent thrombosis is associated with the development of venous valvular insufficiency, an important risk factor for the development (albeit an imperfect correlate[203]) of PTS. The prevalence of thrombus persistence despite adequate anticoagulation in neonatal VTE has ranged from 12% in premature newborns with CRT[183] (representing one of eight patients with VTE, in whom thrombus extension led to progressive SVC syndrome and death) to 62% in full-term neonatal VTE survivors.[119] Among primarily older children, the prevalences of persistent thrombosis have ranged broadly from 37% to 68% in the few longitudinal studies to date that have systematically evaluated thrombus evolution radiologically.[118,141]

Prognostic Indicators. The ability to predict clinically relevant long-term outcomes of VTE at diagnosis and during the acute phase of treatment is essential to a future risk-stratified approach to antithrombotic management in children. Historically, few prognostic indicators have been defined in pediatric VTE. The presence of inherited anticoagulant deficiencies in children with incident VTE has been associated with an increased risk of recurrent VTE.[204] The presence of multiple thrombophilia traits in children with unprovoked (i.e., spontaneous) VTE has been associated with an increased risk of recurrent VTE.[188] In addition, the radiologic finding of complete veno-occlusion at diagnosis of DVT has been associated with an increased risk of persistent thrombosis[205] (which in turn has been associated with the development of venous valvular insufficiency,[203] as noted previously). Plasma FVIII activity greater than 150 U/dL and D-dimer concentration greater than 500 ng/mL at the time of diagnosis of VTE in children, as well as after 3 to 6 months of standard anticoagulation, have been defined as markers of a composite adverse thrombotic outcome, characterized by persistent thrombosis, recurrent VTE, and the development of PTS[118]; similar prognostic findings have been observed in adult VTE.[206-208] Other factors suggested to be associated or possibly associated with development of post-thrombotic syndrome, using a standardized and validated pediatric instrument in recent studies, include an acutely positive dilute Russell viper venom test for the LA in patients treated with conventional anticoagulation,[209] and in mechanically thrombolysed patients have included the diagnosis of May-Thurner or Paget-Schroetter syndrome and a lag time from symptom onset to lytic intervention exceeding 10 days.[153]

Arterial Ischemic Stroke

Epidemiology

The incidence of perinatal and neonatal arterial ischemic stroke (AIS) has been estimated from the U.S. National Hospital Discharge Survey at approximately 18 per 100,000 per year, or 1 in 5000 live births annually.[210] The rate of stroke in later childhood is approximately one tenth of that for the neonatal period, at approximately 2 in 100,000 children per year in the U.S.[211] Similar estimates have been provided by the Canadian and Swiss pediatric stroke registries.[212,213] However, just as for VTE in children, these epidemiologic data for pediatric AIS likely represent underestimates because of the relatively low index of suspicion for cardiovascular and cerebrovascular events in children compared with adults, as well as because of inaccuracies engendered by International Classification of Diseases, 9th revision (ICD-9) coding.[214]

Etiology

The causes of AIS in children are less well characterized than in adults, largely because of the challenges posed by the lower incidence of the disorder in the pediatric population. Whereas hypertension, diabetes, smoking, and hypercholesterolemia are prominent cerebrovascular disease risk factors in adults, in children sickle cell disease, infection, cerebral arteriopathy,[215,216,217] head and neck trauma (with or without identified arterial dissection),[218-220] congenital cardiac disease, previous transient ischemic attack,[221] and thrombophilia[221-225] appear to be the most prevalent identified risk factors for AIS. Whether anemia and polycythemia are independent risk factors for pediatric AIS, or instead constitute epiphenomena of underlying acute and chronic diseases, remains unclear. The subsequent discussion focuses principally on AIS in children without sickle cell disease; for a detailed discussion of AIS in children with sickle cell disease, see Chapter 20.

Arteriopathy in pediatric AIS may be characterized by arterial dissection, narrowing, thrombosis, and irregular arterial contour (suggestive of possible arteritis). Overall, arteriopathy may be identified in as many as one half of non-neonatal AIS cases.[226] Dissection has been demonstrated in 7% to 20% of children with acute AIS.[221,226] The distinction between dissective and nondissective causes of arterial narrowing and thrombosis may be difficult, with variables including the imaging technology employed (e.g., CT with angiography, magnetic resonance angiography, cerebral angiography), the timing in relation to the event, and the experience of the neuroradiologist. Dissection may be caused by head or neck trauma or may be spontaneous; limited data suggest that the prevalence of underlying connective tissue disorders may be increased among AIS cases that are associated with spontaneous dissection, although further controlled studies are needed.[227] Although some studies have indicated that antecedent head trauma appears to be prevalent among pediatric AIS cases, minor head trauma is not infrequent in active children, and there is also considerable potential for recall bias in such studies. A minority of cases of childhood AIS with arteriopathy represent moyamoya syndrome (defined as stenosis in the terminal portion of the internal carotid arteries bilaterally with the formation of collateral arteries, producing the classic angiographic “puff of smoke”) or possible moyamoya syndrome (characterized as either unilateral stenosis in the terminal segment of an internal carotid artery with collaterals or the presence of bilateral stenosis of the terminal portion of the internal carotid arteries without collaterals[217]). Other causes of nondissective cerebral arteriopathy in children include a history of recent varicella zoster infection within the previous year,[198] neurofibromatosis type 1, and cranial irradiation for malignancy.[217,228] Despite the high prevalence of arteriopathy in AIS, its etiology in most cases remains unclear and not attributable to moyamoya syndrome, dissection, or defined infections such as varicella. Efforts to further define the etiologies and natural history of arteriopathic AIS are ongoing through the International Pediatric Stroke Study (IPSS) group.

Infection as an underlying cause for pediatric AIS has been classically associated with tuberculous meningitis, human immunodeficiency virus infection, and primary herpes simplex and varicella virus infection as well as secondary herpes zoster and varicella zoster infections. Local bacterial and fungal infections of the head and neck may also contribute to the etiology of AIS in some pediatric patients. The pathophysiologic mechanisms of infection-associated AIS in children may include direct angioinvasion by the pathogen, local arteritis without direct angioinvasion, and systemic inflammatory and hypercoagulative responses. It is likely that in many instances more than one process contributes to the genesis of AIS. Based on the challenges of etiologic classification in childhood-onset AIS, Bernard and colleagues in the IPSS group have proposed an anatomic-based classification system, the CASCASE criteria, which largely reflect the presence or absence of cardiac abnormalities on echocardiography or ischemic involvement of multiple arterial territories on neuroimaging in support of cardioembolism, as well as the distribution of any aortic, cervical, or cerebral arterial abnormalities in support of dissection, moyamoya syndrome, and the unilateral focal cerebral arteriopathy so frequently observed in childhood-onset AIS.[229]

Thrombophilia Risk Factors

Thrombophilia may contribute to AIS risk via arterial thrombosis or by cerebral embolism of a venous thrombus by way of a cardiac lesion with right-to-left shunt. Thrombophilia risk factors in pediatric AIS include anticoagulant deficiencies (particularly deficiency of protein C[222]), elevated plasma levels of lipoprotein(a),[230] and hyperhomocysteinemia.[231,232] In some cases of AIS following acute varicella infection, antibody-mediated acquired protein S deficiency (i.e., anti–protein S antiphospholipid antibody) has been demonstrated.[233] It is likely that, as is the case for VTE in children, anticoagulant deficiencies are most commonly acquired in the setting of pediatric AIS and are most often parainfectious. However, as in VTE, severe congenital anticoagulant deficiencies associated with AIS may be most likely to present at an early age. Markedly elevated levels of homocysteine are classically associated with metabolic disorders such as homocysteinuria (caused by cystathionine β-synthase deficiency), and appears to be rare among individuals possessing the thermolabile variant of methylenetetrahydrofolate reductase (MTHFR C677T) in countries in which routine folate supplementation of the diet is undertaken. Therefore most evidence suggests that this highly prevalent polymorphism is not an independent risk factor for AIS. Although a single-institutional U.S. study[234] may contradict this evidence, no contemporaneous control group was employed, and further study is necessary. It remains possible that an alternative mechanism to hyperhomocysteinemia may mediate the AIS risk, if substantiated. With regard to lipoprotein(a), a recent U.S. study failed to substantiate the meta-analysis findings that were largely derived from German cohorts but did find elevated lipoprotein(a) as well as small apo(a) isoform size to be risk factors for recurrence of childhood-onset AIS.[235]

Clinical Presentation

The clinical presentation of AIS in neonates and older children largely depends on the territory and extent of the CNS affected by ischemia or infarct. The most common presentation for perinatal and neonatal AIS is seizure, sometimes associated with subtle hemiparesis when AIS involves a unilateral middle cerebral artery (MCA) distribution. Apnea and poor feeding in a term infant should also raise concern for possible perinatal or neonatal AIS. Prenatal MCA-distribution AIS, by contrast, is frequently asymptomatic until noted by parents as one-sided weakness, spasticity, early handedness, or disuse as development of motor activity progresses, frequently with asymmetric gross motor delay between 4 and 12 months of age.

The presentations of acute AIS occurring after the neonatal period (i.e., childhood-onset AIS) include acute- or subacute-onset focal neurologic deficit (e.g., hemiparesis, cranial nerve palsy, dysphasia, incoordination), severe headache, or unexplained new-onset seizure, sometimes accompanied by altered mental status. In cases of dissection-associated AIS in children, a recent history of head or neck trauma is common (see also "Etiology," in this section). Interestingly, a single-center retrospective series of AIS in non-neonatal children found that a "non-abrupt" pattern of neurologic symptoms and signs (including those in whom the maximum severity of symptoms and signs in acute AIS developed more than 30 minutes from the time of symptom onset, the presentation of symptoms and signs was waxing and waning or was preceded by recurrent transient symptoms and signs with intercurrent resolution) was significantly associated with findings of arteriopathy on diagnostic neuroimaging.[236] Ischemic stroke that is not clearly arterial in distribution may result from global hypoxic-ischemic injury (e.g., with watershed distribution), a sequela of CSVT (e.g., symmetrical parasaggital infarction), or metabolic in etiology. A classic example of ischemic stroke of metabolic etiology occurs in mitochondrial myopathy, encephalopathy, lactic acidosis, and strokelike episodes (MELAS). MELAS is caused by mitochondrial DNA defects encoding tRNA involved in the generation of ATP via the electron transport chain in the mitochondrion. The clinical presentation of MELAS is ischemic stroke, often recurrent in nature, in the preschool or school-aged child. Imaging most often reveals persistent ischemia or infarct in the posterior cerebral hemispheres, with relative sparing of deep white matter; the affected territory often results in hemianopia.[237] Unlike the cerebral lesions in acute AIS, acute abnormalities at the time of stroke in MELAS are bright on apparent diffusion coefficient (ADC) maps of diffusion-weighted MRI.[238] Associated symptoms and signs in MELAS, which are of varying severity and penetrance in affected individuals owing to threshold effect and heteroplasmy in mitochondrial DNA disorders,[239] include short stature, hearing loss, recurrent seizure, proximal muscle weakness, and optic atrophy.[237]

Diagnosis

Imaging Studies. The diagnostic evaluation for suspected acute AIS in children involves either urgent CT of the head with CT angiogram (CTA) of the head and neck or, alternatively, MRI of the brain with diffusion-weighted imaging and magnetic resonance angiography (MRA) of the head and neck. Whereas routine CT and MRI evaluates for ischemia, hemorrhage, mass/mass effect, and other non-AIS pathologies, the addition of angiography permits evaluation for arteriopathy, including dissection, stenosis, irregular contour, or intraarterial thrombosis. CT is often more readily available on an urgent basis than MRI; however, CT engenders greater radiation exposure than MRI (especially if angiography is performed) and is less sensitive for the diagnosis of AIS, especially in the acute phase of ischemia. For the latter reason, if CT is performed initially and is unremarkable in the setting of an acute focal neurologic deficit of unclear etiology, this imaging should be followed by MRI of the brain with diffusion-weighted imaging and MRA of the head and neck. In circumstances in which the presence or extent of arteriopathy is unclear by MRA and/or CTA, or in cases of moyamoya syndrome, the more invasive approach of cerebral angiography is warranted to establish a definitive diagnosis and guide subsequent management.

The pattern of ischemia and infarction may be informative with respect to etiology and consequent management of AIS. For example, multifocal infarction may suggest a thromboembolic etiology of AIS. Subcortical distribution of ischemia and infarct may suggest small arterial disease. Watershed distribution of ischemia and infarct may suggest an alternative diagnosis of hypoxic-ischemic injury related to hypotension and other global causes of poor perfusion.

An additional important component to diagnostic imaging in pediatric AIS is echocardiography (either transthoracic with peripheral intravenous saline injection or transesophageal) to evaluate for right-to-left shunting cardiac lesion, with potential implications for management.

Laboratory Studies. Diagnostic laboratory evaluation in pediatric acute AIS involves a complete blood count, toxicology screen, complete metabolic panel, erythrocyte sedimentation rate/C-reactive protein, β–human chorionic gonadotropin testing in post-menarchal females, fasting lipid profile, and thrombophilia assessment (see the section on VTE diagnosis in this chapter). When APA results are positive in the neonate with AIS, it is informative to evaluate for APA in the mother to establish a possible etiology of vertical (i.e., transplacental) transmission of immunoglobulin G APA. In childhood-onset AIS with the common finding of unilateral focal cerebral arteriopathy, consideration should be given to infectious disease investigation, including serology for such viral infections as varicella-zoster virus, herpes simplex virus, Epstein-Barr virus, parvovirus, and enterovirus; a thorough workup may also include enteroviral cultures of the mouth and rectum and blood testing for *Helicobacter pylori*. If there is associated meningitis or in the presence of relevant clinical risk factors, tuberculosis testing should also be undertaken. In the setting of arteritis, rheumatologic evaluation should be considered and should include testing of antinuclear antibodies and other markers as warranted. In certain circumstances additional studies may be warranted, including evaluation for metabolic (including mitochondrial DNA-based) disorders, particularly in AIS with encephalopathy of unclear etiology, nonarterial distribution, lactic acidosis, or other multisystem disorders of unclear etiology (e.g., hearing loss, myalgia, endocrinopathy).

The role of lumbar puncture is controversial, especially when weighed against the need to withhold anticoagulation periprocedurally. Unfortunately, the circumstances in which risk for AIS progression or early recurrence is among the greatest (e.g., acute or subacute period of AIS with vasculopathy), and therefore in which maintenance of effective anticoagulation may be most critical, is also the same circumstances in which lumbar puncture for infectious disease investigation would be among the most informative (yet requires suspension of anticoagulation).

Treatment

Initial management of AIS in children must emphasize appropriate control of blood pressure, temperature, glycemia, oxygenation, and hydration. Unfortunately, there is no evidence from clinical trials on which to base specific interventions for acute AIS in children who do not have sickle cell disease. Nevertheless, pediatric AIS treatment recommendations[139,240] have been developed on the basis of registry and cohort study data in neonates and older children, as well as to some extent on evidence extrapolated from studies in adult AIS. Acute antithrombotic therapy use and regimens in childhood-onset AIS are highly variable worldwide and within the United States.[241]

In the absence of suspected cardioembolism or potent thrombophilia, antithrombotic therapy is rarely employed in perinatal and neonatal AIS, as appropriate to the low risk (cumulative incidence of approximately 3% at a median follow-up duration of 3.5 years[242]) of recurrent AIS or VTE. Therefore for most cases of perinatal AIS advancing the knowledge of acute and subacute neuroprotective interventions is likely to be more beneficial than employing therapeutic strategies aimed at risk reduction of recurrent AIS.

In contrast to neonates, antithrombotic intervention is generally recommended as secondary AIS prophylaxis in older children with acute AIS, given a relatively high recurrence rate (cumulative incidence of approximately 40% at 5 years[221]). A nonrandomized prospective cohort-based study of LMWH versus aspirin as secondary AIS prophylaxis detected no significant difference in the cumulative incidence of recurrent AIS between these two therapies.[243] The optimal antithrombotic regimen and duration for a given CASCADE subtype of childhood-onset AIS remain unclear in the absence of evidence from randomized controlled trials. Antiplatelet therapy with daily aspirin is widely used in childhood AIS, with variable intensity (e.g., 1 to 5 mg/kg per dose) and duration (3 months, 1 year, indefinitely). Patients who experience recurrent AIS while on antiplatelet therapy should be considered for therapeutic anticoagulation.

Pediatric AIS with moyamoya syndrome presents a particular challenge to optimal management. Anticoagulation and antiplatelet agents have been considered as possible therapies. However, given heightened risks for both intracerebral hemorrhage and recurrent AIS, neurosurgical approaches at revascularization (including indirect means, such as encephaloduroarteriomyosyangiosis [EDAMS],[244] and direct means, such as superficial temporal artery branch-to-middle cerebral artery branch [STA-MCA] and anterior cerebral artery branch [ACA] bypass[245]) are generally preferred, and anticoagulation or antiplatelet therapy is perhaps best reserved for children with appropriately defined "possible moyamoya" in the absence of recurrent symptoms or recurrent AIS- or transient ischemic attack–related events.

Thrombolytic approaches have been employed in isolated cases of pediatric AIS.[246] Because only a minute proportion of cases of acute AIS in children are diagnosed within the first few hours of symptomatic onset, a multicenter collaborative clinical trial approach with stringent uniform exclusion criteria will be required to address whether adult evidence for a beneficial role of systemic tPA administration in the immediate period after onset of AIS may also apply to children. An early-phase dose-finding trial is currently underway through the IPSS group.[247] Other thrombolytic approaches include interventional pharmacomechanical thrombolysis and thrombectomy for acute AIS associated with arterial thrombosis. However, technical limitations (i.e., size constraints) are posed by small-caliber pediatric cerebral vasculature, and pediatric recommendations reflect the similar cautions found in adult recommendations.[192]

In the subacute period after AIS in children and over the long term, treatment to optimize outcomes includes rehabilitation services (e.g., physical, occupational, and speech therapy) and neuropsychological interventions (e.g., educational, vocational, and mental health services). The need for these services should be assessed on a case-by-case basis and provided in accordance with the findings of comprehensive multidisciplinary assessments involving the expertise of pediatric neurology, rehabilitation medicine, and neuropsychology staff members. Furthermore, the impact of rehabilitative and neuropsychological interventions on the progress and future needs of the pediatric AIS patient should be regularly reassessed in extended follow-up.

Outcomes

Short-term adverse outcomes of AIS include death caused by uncontrolled increased intracranial pressure with uncal herniation, status epilepticus, or hemodynamic instability in extensive intracardiac thrombosis associated with cardioembolic AIS; major hemorrhagic complications, including those related to antithrombotic interventions as well as postischemic CNS hemorrhage; acute neurologic deficits; and early recurrence of AIS. Findings from the IPSS indicate that neurologic deficits are present at hospital discharge in approximately 70% of cases of childhood-onset AIS.[241]

Long-term outcomes of AIS in children include residual neurologic deficits, cognitive impairments, and recurrent AIS. These outcomes, stratified by diagnosis in the neonatal period versus older childhood, are summarized in Tables 35-4 and 35-5 based on data from selected published studies.[198,212,221,226,242,248,249,250,251,252] In brief, death caused by perinatal or neonatal AIS is quite rare, and for childhood AIS the case-fatality rate (i.e., cumulative incidence) ranges between 2% and 16% in various analyses, although the period over which death was attributable to AIS has not been well delineated in most studies. The risk (i.e., cumulative incidence) of recurrent AIS in perinatal or neonatal AIS is approximately 3% at a median follow-up duration of 3.5 years,[242] whereas the risk for recurrence after non-neonatal AIS varies widely between 19% and 40% at a fixed follow-up duration of 5 years. With regard to neurologic and rehabilitative (e.g., neuromotor, speech) outcomes, the prevalence of neuromotor deficits after perinatal or neonatal AIS varies widely between 36% at a median follow-up of 19 months and approximately 60% at average follow-up times 2 to 6 years across studies. Furthermore, the prevalence of either hemiplegia or asymmetric tone without hemiplegia has been shown in one study to be 30% at approximately 5 to 7 years of age.[252] By comparison, the prevalence of persistent neuromotor deficits for AIS diagnosed in

†Expressive speech deficits were evaluated in one study,[62] with a defined prevalence of 18%.

later childhood is approximately 70% at average follow-up durations ranging from 6 months to 2.5 years across studies. Expressive speech impairments have been noted in 12% of perinatal or neonatal and 18% of non-neonatal AIS cases in one study.[198] As for neuropsychologic outcomes, cognitive or behavioral deficits have been discerned in a few of the aforementioned studies in 3% to 14% of children with perinatal or neonatal AIS at 2 to 6 years average follow-up and in 17% of children at 2 years follow-up in whom AIS occurred in later childhood.

Prognostic Indicators. As in pediatric VTE, the ability to predict clinically relevant acute and long-term outcomes of AIS at diagnosis and during the acute phase of treatment is essential to the development of appropriate management paradigms in children. However, such efforts have been particularly challenged by the relative infrequency of pediatric AIS cases and the heterogeneity in etiologies and AIS subtypes in this complex disorder. In perinatal or neonatal ischemic stroke, a cohort study[253] of 24 neonates with ischemic stroke, including mostly MCA-territory AIS cases but some with primarily watershed area involvement, suggested that an abnormal background on early neonatal encephalography (as opposed to focal epileptiform discharges) and a distribution that includes a cerebral hemisphere along with both the internal capsule and basal ganglia (as opposed to only one or two of these regions) serve as factors that are each associated with the development of a persistent neurologic deficit. The deficits consisted of either hemiplegia or asymmetry of tone without hemiplegia. These data were subsequently substantiated at later follow-up in early childhood.[252] In a smaller series the presence of signal abnormalities in the posterior limb of the internal capsule or the cerebral peduncles on magnetic resonance with diffusion-weighted imaging and apparent diffusion coefficient mapping in acute perinatal or neonatal AIS was recently found to be associated with the development of either hemiplegia or asymmetry of tone without hemiplegia at a median follow-up of greater than 18 months[254] and are supported by similar findings in a separate cohort at a median follow-up of 5.5 years. More recently, the use of computer-assisted quantitation of degree of descending corticospinal tract signal abnormality on magnetic resonance with diffusion-weighted imaging in a series of 14 neonates with AIS demonstrated that the percentage of cerebral peduncle affected and the total length of descending corticospinal tract involved correlates with the development of hemiparesis.[251] Although correlates of neuromotor outcome in perinatal and neonatal AIS are becoming better defined, predictors of recurrent stroke in this group have been elusive, particularly given the infrequency of recurrent AIS after perinatal or neonatal AIS. In childhood-onset AIS, an IPSS analysis in 2009 identified arteriopathy, bilateral ischemia, and decreased consciousness at stroke presentation or diagnosis to each be independently prognostic of a composite acute adverse outcome of death or neurologic deficit at hospital discharge.[241] With regard to AIS recurrence, a single-center retrospective study in the 1990s demonstrated a statistically significant increase in the odds of recurrent AIS among patients with more than one AIS risk factor (e.g., arteriopathy, thrombophilia traits, cardiac disorders, infection) identified at the time of the acute event compared with children who had one or no risk factors.[252] In addition, patients with moyamoya syndrome are at greatly increased risk for recurrent AIS and persistent neurologic deficits.[221,226,255] In one large single-center cohort study of mixed prospective-retrospective design,[221] moyamoya was one of only two independent risk factors for recurrent ischemic events (consisting of AIS, transient ischemic attack, or death with reinfarction). The association of arteriopathy with increased risk of recurrent AIS in children has been demonstrated in a U.S. population-based cohort,[250] confirming prior findings from a large multicenter German prospective cohort study of childhood AIS.[242] In the German study elevated serum levels of lipoprotein(a), congenital protein C deficiency, and arteriopathy were each found to be independent risk factors for recurrent AIS. Although APAs were not evaluated in the multivariate model of the German cohort study, a two-center British-Canadian cohort study of non-neonatal AIS, including 185 children, reported that no increased risk for recurrent AIS appears to exist with respect to persistently positive immunoglobulin G–type anticardiolipin antibody titers.[256] Although the statistically insignificant unadjusted difference in 3-year recurrence rates between anticardiolipin immunoglobulin G–positive and –negative groups at 38% versus 26% might nevertheless be considered clinically meaningful, the difference in proportional hazard functions for AIS recurrence between the two groups was also not statistically significant after adjustment for covariates of AIS etiologies and treatment types. However, few cases of high-titer antibodies were represented in the cohort. Clearly, further basic and translational research is needed to discern which subtypes of anticardiolipin antibodies may be most arteriopathic and thrombogenic and will likely involve secondary characterization of APAs using functional assays. With regard to lipoprotein(a), as noted earlier, its importance as a prognostic factor for recurrent childhood-onset AIS from the German cohort was recently substantiated in a U.S. cohort, which also identified small apo(a) isoform size as a prognostic factor for recurrence.[241]

Future studies should seek to validate the predictive capacity of these potentially quite meaningful associations in pediatric AIS cohorts distinct from those in which these associations have been derived. Collaborative multicenter cohort studies and trials groups, such as the IPSS group, offer optimism for the establishment of more robust evidence of predictors of outcome in neonatal and childhood AIS according to common etiologies and vascular pathologies; these data will help clinicians optimize risk-stratified approaches to the management of pediatric AIS in future years.

CHAPTER 36

Transfusion Medicine*

Steven R. Sloan

CHAPTER OUTLINE

RED BLOOD CELL TRANSFUSIONS
- Indications for Transfusion
- Packed Red Blood Cells
- Leukoreduction of Red Blood Cells
- Irradiation of Red Blood Cells
- Immunologic Considerations
- Compatibility Procedures
- Selection of Blood for Transfusion to Patients with Blood Group Alloantibodies
- Selection of Blood for Transfusion to Patients with Blood Group Autoantibodies
- Adverse Effects of Transfusion

PLATELET TRANSFUSIONS
- Indications for Transfusion
- Platelet Units
- Platelet Dosing
- Platelet Refractory State
- Preventing Platelet Alloantibodies

GRANULOCYTE TRANSFUSIONS

PRINCIPLES OF HEMATOPOIETIC CELLULAR THERAPY
- Hematopoietic Cell Sources
- Infusion-Related Toxicities
- Component Assessment
- Processing and Storage of Hematopoietic Progenitor Cell Components
- Future Directions

APHERESIS
- Donor Apheresis
- Therapeutic Apheresis
- Manual Apheresis
- Automated Apheresis
- Unique Aspects of Apheresis in Pediatrics
- Indications

ERYTHROCYTAPHERESIS (RED BLOOD CELL EXCHANGE) FOR SICKLE CELL DISEASE
- Acute Chest Syndrome
- Stroke
- Priapism
- Red Blood Cell Exchange for Chronic Transfusion
- Normovolemic Red Blood Cell Transfusion

LEUKAPHERESIS

PERIPHERAL BLOOD PROGENITOR CELLS

EXTRACORPOREAL PHOTOPHERESIS

PLASMA EXCHANGE
- Autoimmune Disorders
- Other Coagulopathies
- Renal Disease
- Hypercholesterolemia
- Transplantation
- Disseminated Intravascular Coagulation
- Special Applications and Selective Adsorptions

CONCLUSION

Transfusion medicine focuses on the administration of blood, blood components, and purified blood proteins to patients for therapeutic purposes. Red blood cells (RBCs) are the most frequently used blood component. In this chapter RBC transfusions are discussed first, and issues that pertain to all transfusions, such as transfusion reactions and transfusion-transmitted diseases, are discussed in this section. Platelets are often transfused to some patients, such as those receiving oncologic treatment, and are discussed in the next section of this chapter. While not a traditional blood component prepared by blood banks, hematopoietic progenitor cells are a blood derived cellular component that are being infused with increasing frequency over the past two decades. Although these cells are often said to be transplanted rather than transfused, they are also discussed in this chapter. Finally, granulocyte components collected by apheresis for transfusion and other apheresis procedures that allow for the simultaneous removal and transfusion of blood components are discussed at the end of this chapter.

---

*Revised from a chapter in an earlier edition whose authors included David F. Friedman, Grace Kao, Richard M. Kaufman, and Leslie Silberstein.

RED BLOOD CELL TRANSFUSIONS

Indications For Transfusion

The primary function of RBCs is to bind oxygen as the RBCs circulate through the pulmonary bed and release oxygen in the capillaries at a sufficiently high pressure for tissue diffusion. The configuration of the oxyhemoglobin dissociation curve provides for proper diffusion as long as only part of the oxygen is released during capillary transit. The oxygen tension of fully oxygenated blood in the arteries is approximately 100 mm Hg; a release of 20% of the oxygen in the capillaries maintains a pressure of 40 mm Hg, which is sufficient to propel oxygen to all cells within a truncated cone segment around the capillary.[1] RBCs compensate for a loss in oxygen-carrying capacity relatively rapidly by a shift in the oxyhemoglobin dissociation curve to the right, which decreases oxygen's affinity for hemoglobin (Hb). In addition, cardiac output increases. On a more chronic basis, blood volume, the size of the vascular bed, and the rate of production of RBCs increases. These compensatory mechanisms permit states of mild to moderate anemia without significant symptoms.

For most patients the only indication for RBC transfusion is to provide a patient with sufficient RBCs to prevent or reverse tissue hypoxia caused by insufficient compensation. One large multicenter randomized controlled study of adult critically ill patients is probably applicable to some pediatric patients, especially adolescents.[2] That trial compared a liberal transfusion strategy in which patients received RBC transfusions when their Hb level was below 10 g/dL to a restrictive transfusion strategy in which patients were transfused when their Hb level was below 7 g/dL. Among patients younger than 55 years old, those who were transfused according to the more restrictive strategy had a significantly lower 30-day mortality rate. A similar study of stable critically ill pediatric patients in intensive care units found similar clinical outcomes but fewer RBC transfusions in patients transfused at an Hb concentration at or below 7 g/dL compared with patients transfused at an Hb concentration at or below 9.5 g/dL.[3] In that study patients could be transfused for active bleeding or hemodynamic instability even if their blood Hb concentration had not reached the assigned trigger.

Two prospective randomized controlled studies have compared transfusion strategies for low-weight premature infants. The triggers used for transfusion depended on the oxygen support requirements in both studies[4,5] and also on the baby's age in one of the studies.[5] Because neonates often receive multiple aliquots from the same RBC unit, there was no statistical difference in donor exposure between the liberal and restrictive transfusion groups in either study. One study by Bell and colleagues found that neonates on the liberal transfusion strategy were less likely to develop intraventricular hemorrhage or periventricular leukomalacia.[4] However, a follow-up study of these patients when they were between 8 and 15 years old found better neurocognitive development in the children transfused more conservatively.[6] In contrast, the other larger multicenter study by Kirpalani and coworkers found no differences in short-term outcomes between patients assigned to liberal and restrictive groups, but a follow-up study of the patients when they were 18 to 21 months age suggested cognitive delay in those transfused more conservatively.[5,7] Taken together, these studies suggest that a more liberal transfusion strategy might be advisable. A liberal RBC transfusion protocol might protect against obvious brain injury without significant risk in the neonatal period. Additionally, the larger of the two randomized studies suggested better neurocognitive outcomes with a more liberal use of RBC transfusions.

Children who are chronically anemic as a result of thalassemia may also benefit from a more liberal transfusion policy. These patients benefit from a hypertransfusion program that maintains their Hb concentration above 9 to 10 g/dL. Hypertransfusion of these patients allows them to attain normal height and weight and reduces the risk of hepatosplenomegaly, osteoporosis, and cardiac dilation.[8-12] Transfusions benefit these patients by increasing tissue oxygenation and particularly by suppressing endogenous erythropoiesis.

Acute Blood Loss

RBC transfusions are frequently used to replace blood loss either in the operating room or after trauma. In practice, diagnosis of the presence and degree of blood loss is quite difficult, especially in a young otherwise healthy child. In fact, a child may sustain a relatively large hemorrhage with few external signs of distress. Signs of impending shock, such as pallor, anxiety, and tachypnea, are frequently subtle and easily overlooked or attributed to other causes. By the time signs of cardiovascular compromise become evident (i.e., stupor, tachycardia or bradycardia, hypotension, coolness of the extremities, weak peripheral pulses, and decreased capillary filling), the patient has most likely lost at least 25% of the total blood volume. Hypotension is one useful clinical sign of moderate to severe blood loss. Patients who have lost more than 25% of their blood volume frequently manifest age-related systolic hypotension: less than 65 mm Hg (younger than 4 years of age); less than 75 mm Hg (5 to 8 years of age); less than 85 mm Hg (9 to 12 years of age); and less than 95 mm Hg (adolescents and adults).

Chronic Transfusion Therapy

In chronic anemia the body is deficient in red cells, whereas the plasma volume is normal or increased so that the total blood volume is normal. Box 36-1 lists the childhood conditions that are likely to require intermittent or long-term transfusion therapy.

The following guidelines apply when planning for chronic transfusions (months to years):

1. If possible, transfusion should be avoided or minimized by aggressive treatment of the underlying disorder (e.g., recombinant human erythropoietin [r-HuEPO] administration for patients on dialysis or with chronic renal failure).
2. Leukocyte-reduced RBCs should be used to avert or delay sensitization to leukocyte alloantigens, the

Box 36-1 Diseases Requiring Intermittent or Chronic Red Cell Transfusion in Childhood

- Aplastic anemia
  - Constitutional
  - Acquired
  - Oncologic (leukemia, solid tumors)
  - Diamond-Blackfan anemia
  - Transient erythroblastopenia

most common cause of febrile nonhemolytic transfusion reactions.

3. RBCs should be administered in an amount sufficient to prevent symptomatic anemia and allow for normal growth.
4. The patient's iron status should be monitored through determination of serum ferritin, iron, iron-binding capacity, and liver iron stores (see Chapter 21 for more information).

Packed Red Blood Cells

A packed cell product is the component of choice for replacement during surgery, RBC loss, and chronic transfusion therapy. Most RBC units contain an additive nutrient solution such as Adsol or Nutricel and have a hematocrit concentration of 50% to 60%, whereas RBC units collected and stored in citratephosphate-dextrose-adenosine (CPDA-1) have an average hematocrit concentration of approximately 75%.[13] Additives vary in their composition and contain some combination compounds, including dextrose, citrate, mannitol, and adenine. Although no systemic pediatric risk has been demonstrated for additives, some institutions avoid using them or remove them before transfusing in large quantities to neonates.[14]

Blood Storage

During storage RBC metabolism continues, and some leakage through RBC membranes occurs. This results in decreasing plasma dextrose and increasing plasma potassium. These changes are acceptable for most transfusions, but in some situations the increased potassium in solution may cause problems. In these cases fresh blood (less than 7 to 10 days old) may be beneficial. This is indicated when small patients receive large amounts of blood, such as neonates receiving exchange transfusions or infants receiving large transfusions rapidly during surgery. However, neonates can tolerate 5 to 20 mL/kg transfusions of older units of RBCs, and some blood banks dedicate a unit of blood for repeated transfusions to one infant to minimize the number of donors to which each infant is exposed.[14] This protocol can lead to transfusion of older RBC units, which are safe for infants, including premature infants.[15]

Leukoreduction of Red Blood Cells

Transfusion of allogeneic cellular blood products is associated with deleterious effects caused by the presence of residual leukocytes. These side effects include alloimmunization to histocompatibility antigens in patients with leukemia, transmission of some viruses, febrile reactions, and graft-versus-host disease (GVHD).[16,17] Filters are used to reduce the number of leukocytes from whole blood, RBCs, and platelets.[18,19] Routine leukoreduction of red cells to less than 5×10^6 leukocytes per unit reduces the frequency of febrile nonhemolytic transfusion reactions in patients who are transfusion dependent.[20,21] The removal of leukocytes from blood also reduces the risk of leukocyte-associated virus transmission, such as cytomegalovirus (CMV). Leukoreduction of RBCs and platelets to a level of less than 5×10^6 has been demonstrated to substantially reduce CMV transmission in neonates and transplant patients.[22,23] However, leukoreduction is not sufficient to prevent transfusion-associated GVHD.

Irradiation of Red Blood Cells

Transfusion-associated GVHD is a rare complication after transfusion of cellular products. Patients who are the most susceptible include premature neonates, some patients with congenital immunodeficiency syndromes, immunosuppressed oncology patients being treated with chemotherapy or irradiation (or both), and patients receiving certain immunosuppressive drugs after solid organ transplantation and certain other indications.[24-26] In addition, normal recipients who are heterozygous for human leukocyte antigens (HLAs) do not reject lymphocytes that are transfused from a donor who is homozygous for one of the recipient's haplotypes.[27] This is not merely theoretic. Transfusion-associated GVHD has developed in normal recipients undergoing surgery who received unirradiated directed donor blood from a first-order relative.[28,29] Because of the wide variety of patients at risk for GVHD, some transfusion services have chosen to irradiate all cellular blood products to ensure that no patient develops this life-threatening complication.

Immunologic Considerations

Multiple antigens that are expressed on erythrocyte cell surfaces can be recognized by the immune system of a transfusion recipient. Before an RBC transfusion, erythrocytes that are immunologically compatible with the patient must be identified. Erythrocyte antigens are polymorphic inherited structural characteristics located on proteins, glycoproteins, or glycolipids on the outside surface of the RBC membrane. Erythrocyte antigens are clinically important in the immune destruction of RBCs in allogeneic blood transfusions, maternal-fetal blood group incompatibility, autoimmune hemolytic anemia, and organ transplantation. The ability to detect and identify antibodies to erythrocyte antigens and identify compatible donor RBCs lacking the specific antigens has contributed significantly to the safe supportive blood transfusion practices used today.

The ABO and H System

The H Antigen. A and B antigens on RBCs are defined by a terminal sugar attached to a carbohydrate chain on membrane glycosphingolipids. The H antigen is the precursor molecule on which A and B antigens are built. The H antigen on RBCs is defined by fucose at the terminus

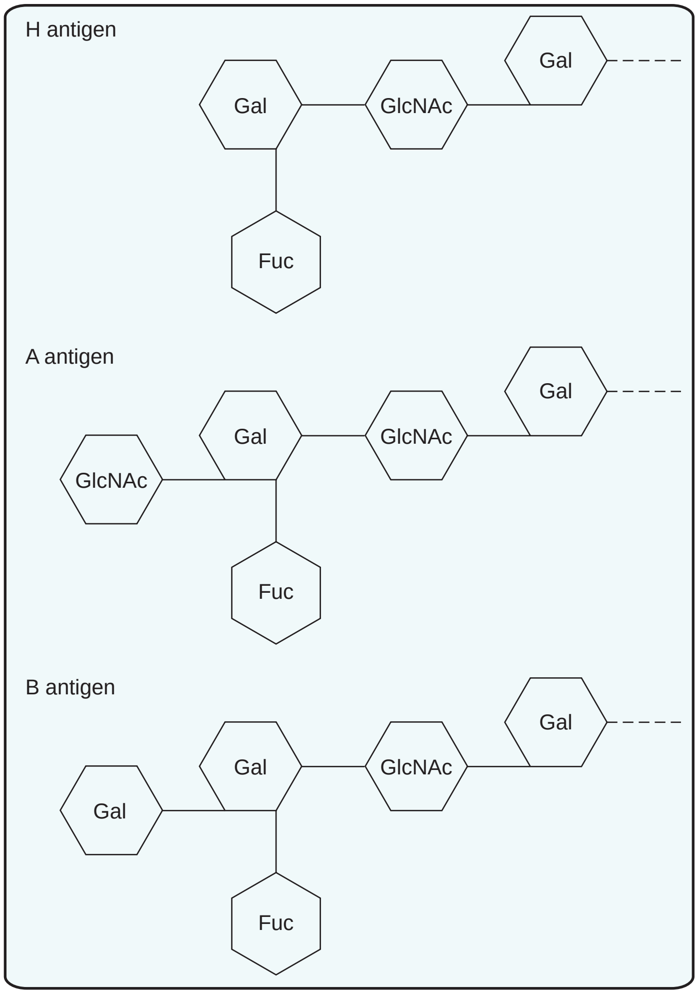

Figure 36-1 Structure of the precursor H structure and the A and B antigens. *GlcNAc, N*-acetylglucosamine.

of carbohydrate chains.[30] Expression of the H antigen is determined by a fucosyltransferase that transfers a fucose to an oligosaccharide side chain that is attached to integral membrane proteins on RBCs. The fucosyltransferase (and thus the H antigen) is present in all persons except those with the rare Bombay (Oh) phenotype.[31]

The A and B Antigens. Transferases responsible for the A or B antigens add *N*-acetyl galactosamine or galactose, respectively, to the precursor chain carrying the H antigen (Fig. 36-1).[30,32-36] The genes for the A and B blood group antigens are codominant because people with both transferases will transfer galactosamine and galactose and thus express A and B antigens. Group O is the amorph of the ABO blood group system. RBCs from group O persons have H antigens but lack A and B antigens.[37]

Although ABO antigens are detectable on the RBCs of 5- to 6-week-old embryos, these antigens are not fully developed until 2 to 4 years of age.[38-41] RBCs from infants carry A, B, and H antigens on linear oligosaccharide chains, which have only one terminus to which the A, B, and H sugars can be added.[30,32,34,42-44] The fact that the A and B antigens are not fully developed at birth may be one reason that ABO hemolytic disease of the newborn (HDN) is usually a mild disease.[44,45] As the infants grow older, the oligosaccharides branch, creating additional termini to which A, B, and H sugars can be added.[35] After the children reach 2 to 4 years of age, expression of A and B antigens remains fairly constant throughout life.

Antibodies to A and B antigens, also known as isohemagglutinins, develop as a result of environmental stimulants, such as bacteria, that carry similar antigens.[46] Because isohemagglutinins are naturally occurring, it is essential to select ABO-compatible blood for transfusion.[47] Indeed, ABO incompatibility is the most frequent cause of fatal hemolytic transfusion reactions.

Isohemagglutinin production begins several months after birth, reaching a peak at 5 to 10 years of age and declining with increasing age.[48] Thus infants younger than 4 months of age who have isohemagglutinins will have acquired them through placental transfer of maternal immunoglobulin G (IgG) anti-A, anti-B, or anti-A,B.[44]

Isohemagglutinins from group A and B individuals are predominantly immunoglobulin M (IgM) that do not usually cross the placenta and cause HDN.[49] However, as group O serum contains IgG isohemagglutins, ABO HDN is most frequently seen in non–group O infants of group O mothers.

The Lewis System

The Lewis antigens, Le^a and Le^b, are not intrinsic to RBCs but are instead carried on plasma glycosphingolipids that are adsorbed onto the RBC membrane.[50] These antigens are structurally related, with the Le^b antigen containing an additional fucose that is not present on the Le^a antigen. Furthermore, the one additional fucose present on the Le^b antigen is not very different from the Le^a antigen. Thus Le^a individuals rarely make anti-Le^b. Hence in most cases Lewis antibodies are made only in individuals who are Le(a–b–).[44]

In most cases Lewis antibodies do not cause hemolysis, and donor RBCs lacking the Lewis antigens do not usually need to be selected.[44] However, rare hemolytic transfusion reactions have been reported when Le^a+ RBCs were transfused to recipients with anti-Le^a.[51] This may occur when the antibody reacts at 37° C. In these cases it is not difficult to identify Le^a– donor units because the RBCs in almost 80% of donors are Le^a–.[52] Anti-Le^a and anti-Le^b are not known to cause HDN. They are usually IgM, and fetal RBCs type Le(a–b–).[44] Interestingly, Lewis antigens are also expressed on *Helicobacter pylori,* a causative agent of gastric ulcers, and play a role in adhesion and colonization of the bacteria in the gastric mucosa.[53,54]

The Ii Collection

The I and i antigens reside in the subterminal portions of carbohydrate chains on glycolipids or glycoproteins of the RBC membrane. The i antigen on fetal RBCs appears when disaccharide units are linked in a straight chain.[55] In the first 2 years of life, many of these linear chains are modified into branched chains.[35] I specificity results at the expense of i antigens when the branched structures appear. Adults have RBCs with predominantly I antigens and little or no i antigen, whereas newborns have RBCs with strong expression of i antigens and small amounts of I antigen.[56]

Anti-I is a common autoantibody that is reactive at room temperature and below and usually produces no hemolysis.[57,58] In cold agglutinin disease, anti-I causes in vivo hemolysis, and such pathologic autoantibodies often react at 30° C in albumin.[59] Adult I-negative RBCs are not readily available for transfusion, and patients with cold agglutinin disease caused by anti-I are transfused with I-positive RBCs through a blood warmer.[44] The titer and thermal range of anti-I is often increased after infection with *Mycoplasma pneumoniae*.[44] The presence of a cold agglutinin caused by an anti-I antibody frequently occurs in *M. pneumoniae* infection, but this is neither a specific nor a sensitive test for this infection.[60] Analogously, cold agglutinins resulting from anti-i antibodies are sometimes present in Epstein-Barr virus infection, but this is neither a sensitive nor a specific test for this infection.[61]

Levels of the i antigen can aid in differentiating Diamond-Blackfan anemia from transient erythroblastopenia of childhood. The i antigen is enhanced on RBCs from patients with Diamond-Blackfan anemia and is absent or of reduced strength on RBCs from children with transient erythroblastopenia of childhood.[62-64] However, the enhanced i antigen associated with Diamond-Blackfan anemia reflects stress hematopoiesis[65] and is not a specific aspect of the disease. In transient erythroblastopenia of childhood, the reduced levels of i antigen reflect the selective suppression of erythropoiesis secondary to infection; however, during recovery from this disorder the patient's marrow is active and the i antigen may be enhanced as a result of hematopoietic stress.[64]

The P System

Like the A, B, and H antigens, the P blood group antigens are defined by sugars added to precursor glycosphingolipids. Antigens in this group include P1, P, and P^K. Among white people, 21% have the P1-negative phenotype, and they commonly produce anti-P1. This cold reactive IgM antibody does not cross the placenta and has rarely been reported to cause hemolysis in vivo.[66] An autoantibody, autoanti-P, is found in patients with paroxysmal cold hemoglobinuria and in some patients with acquired immune hemolytic anemia. It is called the Donath-Landsteiner antibody and is most frequently seen in children.[67] This IgG autoantibody is a biphasic hemolysin that binds to RBCs in the cold and then hemolyzes them when warmed. The patient's serum causes hemolysis of RBCs that have been incubated first in melting ice and then incubated at 37° C.[68] This antibody should be considered when the patient has hemoglobinuria or anemia (or both) and C3 alone is present on the RBCs.

The P antigen serves as a receptor for parvovirus B19[69] and pyelonephritic *Escherichia coli*.[70,71] Persons with the very rare p phenotype lack the antigens P1, P, and P^k and are not susceptible to infection by parvovirus B19.

People with the rare p phenotype may produce anti-P1+P+P^k, a potent hemolytic antibody that can cause immediate hemolytic transfusion reactions.[44,72] This antibody has also been associated with HDN, fetal death, and miscarriages during early pregnancy in women whose RBCs have the p phenotype.[73]

The Rh System

The Rh blood group system includes D, C, c, E, e, and 40 other antigens.[74] The terms *Rh positive* and *Rh negative* refer to the presence and absence of the D antigen, respectively. The D antigen is, after A and B, the most important RBC antigen in transfusion practice. Persons who lack the D antigen do not have anti-D unless they are exposed to D antigen by pregnancy or transfusion. More than 80% of persons who lack the D antigen can produce anti-D after receiving a unit of D-positive donor blood, but only approximately 22% of D-negative patients transfused with D-positive RBCs make an anti-D antibody.[75-77] Although these statistics probably do not apply to infants younger than 4 months of age, some infants probably can respond to the Rh(D) antigen.[78]

The RBCs of 0.2% to 1% of white individuals and a greater percentage of African Americans carry reduced expression of the D antigen known as weak D. Some RBCs expressing weak D may not be detected by routine anti-D reagents, but almost all are detected by a more sensitive test, the indirect antiglobulin test. D and weak D have the same RH (D) protein complex on their surface but weak D RBCs have fewer RH (D) proteins.[79] That is usually due to point mutations in the gene encoding the Rh(D) antigen, the *RHD* gene.[80,81] Most patients of the weak D phenotype can safely receive blood transfusions from individuals who are Rh(D) positive. However, some individuals express a truncated form of the D protein, known as a partial D, and can make an anti-D antibody. Erythrocytes from such an individual may type as D-positive or weak D. Often only reference labs can determine the specific type of weak D that is present, sometimes using molecular techniques.

All D-negative donor blood is tested for weak D by the antiglobulin test to ensure that D-negative patients are not transfused with weak D RBCs that can induce an anti-D antibody that can hemolyze weak D RBCs.[47] Indeed, there are rare reports of fetuses with weak D having HDN when born to a mother with anti-D antibody in her plasma.[44] Weak D donor RBCs are labeled as Rh(D) positive to ensure that Rh(D)-negative individuals do not receive weak D RBCs. Analogously, at birth an infant is designated as Rh(D) negative only when negative results are obtained for routine anti-D and weak D.[47] This ensures that Rh(D)-negative mothers receive postpartum doses of Rh immune globulin if their baby is Rh(D) positive or weak D positive.

Rh antigens are carried on Rh proteins that pass through the RBC membrane 12 times and are encoded by at least two genes on chromosome 1.[82-85] These Rh proteins associate with the RHAG protein that is required for cell surface expression of the Rh antigens. D, C, c, E, and e antigens are associated with specific amino acid substitutions on the Rh proteins.[84,85] Patients with erythrocytes deficient in Rh proteins owing to complex mutations in the Rh locus have a mild spherocytosis and a mildly hemolytic state known as Rh-deficiency syndrome, or Rh null.[86,87] Mutations of the *RHAG* gene result in regulatory-type Rh deficiency (Rh null or Rh mod) associated with mild hemolytic anemia with overhydrated hereditary stomatocytosis showing increased permeabiltity to cations.[88] Although the function of the Rh proteins is unknown, they may play a role in ammonium transport.[89,90]

The MNS System

The M, N, S, s, and U antigens are carried on sialoglycoproteins on the RBC membrane. M and N are encoded by paired allelic forms of the glycophorin A gene *(GPA)* and are the result of amino acid substitutions at residues 1 and 5 of GPA.[91-93] Human RBCs type as M+N–, M–N+, or M+N+, representing homozygosity for M, homozygosity for N, and heterozygosity for both genes, respectively. S and s antigens are encoded by alternative forms of the glycophorin B gene *(GPB)*. GPA and GPB are encoded by homologous genes on chromosome 4q28-q31.[94] GPA binds *E. coli*[95] and plays a role in malarial invasion of RBCs. RBCs lacking GPA, GPB, or GPC are resistant to invasion by *Plasmodium falciparum* to varying degrees.[96]

Anti-M and anti-N can be IgG, IgM, or a mixture of both. These antibodies are usually clinically insignificant and are often present in persons who have not been previously transfused or pregnant. Those antibodies that react at 37° C may cause hemolysis of transfused cells. Antibodies to S, s, and U usually occur after stimulation and are capable of causing hemolytic transfusion reactions and HDN.[44]

The Kell System

The Kell system antigens reside on two transmembrane proteins, the Kell protein and the XK protein, that are linked by a single disulfide bond. The Kell protein is a 93-kd glycoprotein that carries more than 20 antigens, and the XK protein is a 440–amino acid protein that carries just one antigen known as Kx.

The major antigen of the Kell blood group system resides on the Kell protein. This antigen is the K antigen, which is present in 9% of white donors.[72] Anti-K is the most common immune RBC antibody, after those in the ABO and Rh systems. However, because more than 90% of donors are K–, it is not difficult to find compatible blood for patients with anti-K antibodies. The molecular basis of antithetical K and k antigens is an amino acid substitution of methionine to threonine at residue 193 of the Kell protein.[97] This allows for prenatal testing for K and k antigens of amniocytes from a mother whose fetus is at risk for HDN owing to anti-K or anti-k. Antibodies to other antigens on the Kell protein, such as Kp^a, Kp^b, Js^a, and Js^b, are less common but are also clinically significant.[72,98] The Kell protein is a member of a large family of zinc-dependent endopeptidases.[99]

The other protein of the Kell system, the XK protein, carries one antigen, the Kx antigen.[100] The XK protein is encoded by a gene on the X chromosome and is a 444–amino acid integral membrane protein that has some features of a membrane transporter.[101] The absence of membrane XK protein, known as the McLeod phenotype, results in diminished expression of the Kell protein on the membrane and reduced expression of all antigens in the Kell blood group system. The blood of patients with the McLeod phenotype often has a variety of abnormalities, including acanthocytotic erythrocytes, hemolytic anemia, some teardrop erythrocytes, and bizarre poikilocytes.[102] Most patients with McLeod syndrome develop a subclinical myopathy associated with an elevated creatine phosphokinase level.[103] The neuropathy may first manifest as areflexia and is later characterized by basal ganglia atrophy causing dystonic or choreiform movements, psychiatric symptoms, and cognitive changes.[104,105] Most individuals with McLeod syndrome also develop cardiac symptoms, such as dilated cardiomyopathy and arrhythmias.

The *XK* gene is less than 500 kb beyond the chronic granulomatous disease (CGD) locus on the short arm of the X chromosome (p21.1).[106] Consequently, males with deletions encompassing both loci have both CGD and McLeod syndrome.[98] Patients with CGD and McLeod syndrome usually make antibodies to the XK and Kell proteins if they are transfused with RBCs containing the XK and Kell proteins. This can lead to major problems in transfusing these patients.[107] To avoid this problem, McLeod patients should be transfused with blood of the McLeod phenotype. Ko blood that lacks the Kell protein is not appropriate because such RBCs have increased expression of the Kx antigen that is expressed on the XK protein. However, male subjects with McLeod phenotype without concomitant CGD (non-CGD McLeod) do not make anti-Kx and can be transfused with McLeod or Ko type blood.[98,108]

The Duffy System

The Duffy antigens are epitopes present on a cell surface glycoprotein. The Duffy glycoprotein is a chemokine receptor that is expressed on many cell types and can bind a variety of chemokines.[109] Although the Duffy chemokine receptor can bind chemokines, its function is unknown and people lacking the receptor on their RBCs or on all cells are totally healthy.[110]

The two most common alleles in people of European or Asian descent are Fy^a and Fy^b, which differ by a single amino acid substitution. Anti-Fy^a and -Fy^b have been implicated in transfusion reactions.[44] Anti-Fy^a has caused mild HDN, but anti-Fy^b has not been implicated.[44] Anti-Fy^a is commonly encountered, but because one third of donors are Fy(a-), compatible blood is not difficult to find.

The RBCs of many people of African descent lack the Fya and Fyb antigens (Fy[a–b–]) on their erythrocytes. However, the Fy^b allele is usually expressed in lung, colon, and spleen of these individuals.[111] Thus these individuals cannot mount an immune response to the Fy^b antigen but can produce anti-Fy^a.[44,72] In West Africa most black people are Fy(a-b-) as a result of natural selection; these RBCs are resistant to *Plasmodium vivax* malaria because the Duffy protein is a receptor for *P. vivax*.[109,111,112,113]

The Kidd System

The Kidd gene encodes two antigens, Jk^a and Jk^b, which represent a single amino acid substitution (Asp280Asn) in the Kidd glycoprotein.[114] These are usually expressed in one of three phenotypes: Jk(a+b–), Jk(a–b+), and Jk(a+b+). The fourth phenotype Jk(a–b–) is exceedingly rare.[72] Antibodies to both Kidd antigens can cause delayed hemolytic transfusion reactions. Because these antibodies are often weak and may become undetectable over time, they may escape detection in the sensitized patient's serum before transfusion. If the patient is then transfused with antigen-positive RBCs, the anamnestic response causes an increase in the titer of the antibody and hemolysis of the transfused antigen-positive RBCs.[44] Once the antibody is identified, compatible blood is not difficult to find because one fourth of donors are negative for each antigen.

The Kidd glycoprotein is a urea transporter that prevents RBCs from shrinking and swelling as they pass into and out of the high urea concentration of the renal medulla.[115-117] The Kidd urea transporter also prevents RBCs from carrying urea away from the renal medulla and decreasing the urea-concentrating efficiency of the kidney.[117] Individuals with RBCs with the Jk(a–b–) phenotype are unable to concentrate urine as efficiently as people who have the Kidd glycoprotein.[118-120]

The Lutheran System

The Lutheran blood group antigens are carried on a cell surface glycoprotein. The Lu^a antigen is present on the RBCs of 8% of people, whereas the antithetical antigen, Lu^b, is present in more than 99% of random blood samples. Antibodies in this system are variable and are rarely encountered.[44] The glycoprotein carrying these antigens has five extracellular immunoglobulin-superfamily domains that serve as laminin-binding receptors.[121,122] Lu glycoproteins may be involved in the pathogenesis of sickle cell vaso-occlusive crises and may also be involved in the metastasis of certain types of malignancy.[123,124]

About 1 person in 5000 inherits a dominantly acting inhibitor, called In(Lu),[125,125a] which partially suppresses expression of Lu^a and Lu^b such that they are undetectable by standard agglu-tination tests. The Lu(a-b-) phenotype of the dominant type is associated with acanthocytosis but no hemolysis.[125] Patients with the In(Lu) Lu(a-b-) phenotype have abnormally shaped red cells but no hemolysis.[125] The Lu antigens directly interact with spectrin, independently of protein 4.1, which may partially explain the abnormal RBC morphology in some patients with the In(Lu) phenotype.[126] Osmotic fragility of fresh In(Lu) Lu(a–b–) red cells is normal, but during in vitro incubation the cells lose K^+ and become osmotically resistant.

Other Systems

Other systems are included in Table 36-1.[74] Antibodies to antigens in these systems are less common than those described previously, and information regarding their clinical significance is summarized in Table 36-2.

TABLE 36-1 Blood Group Systems with Associated Gene Product

Blood Group System	Gene Product
Carbohydrate Antigens	
ABO	Glycosyltransferase
P	Glycosyltransferase
Lewis	Glycosyltransferase
Hh	Glycosyltransferase
Protein Antigens	
MNS	Glycophorin A, glycophorin B
Rh	D polypeptide *RHCE* polypeptide CcEe polypeptide
Lutheran	Lutheran glycoprotein
Kell	Kell glycoprotein
Kx	Xk glycoprotein
Duffy	Fy glycoprotein
Kidd	Jk glycoprotein
Diego	Band 3 (AE1)
Yt	Acetylcholinesterase
Xg	Xg^a glycoprotein
Scianna	Sc glycoprotein
Dombrock	Glycoprotein (possibly adenosine 5′-diphosphate[ADP]-ribosyltransferase)
Colton	Channel-forming integral protein
LW	Glycoprotein
Chido/Rodgers	C' component 4 (C4)
Gerbich	Glycophorin C, glycophorin D
Cromer	CD55 (DAF)
Knops	CD35 (CRI)
Indian	CD44

Maturation of Blood Group Antigens

Several blood group antigens are not expressed or are only weakly expressed on cord RBCs and usually reach adult levels by 2 years of age. Antibodies to these antigens are unlikely to cause HDN. Cord RBCs do not express Le^a, Sd^a, Ch, Rg, or AnWj antigens. Cord RBCs express the following antigens more weakly than RBCs from adults: A, B, H, I, Le^b, P_1, Lu^a (but not Lu^b), Yt^a, Vel, Do^a, Do^b, Gy^a, Hy, Jo^a, Xg^a, and Bg.[44,72,127]

Clinical Significance of Blood Group Antibodies

A blood group antigen has no immediate untoward effect on blood transfusion. It is the corresponding antibody that has clinical relevance and dictates the need for tests in a transfusion service to detect blood group antibodies.

Antibodies recognizing antigens in the ABO blood group system are by far the most clinically significant.

TABLE 36-2 Clinical Significance of Selected Alloantibodies to Antigens in Blood Group Systems

Antibody	IgG	IgM	Complement	Transfusion Reaction Binding	HDN*
ABO	Some	Most	Common	Mild to severe; immediate	Moderate
MNS					
MN	Some	Some	Rare	Extremely rare	Extremely rare

*The most severe form of hemolytic disease of the newborn (HDN) that has been reported is indicated. Remember that exceptions exist.

With antibodies in the other blood group systems, as a general rule, the more immunogenic an antigen, the more clinically significant its corresponding alloantibody. Other clinically significant antibodies occur in the following order, from most commonly to least commonly encountered in transfusion practice: anti-D, anti-K, anti-E, anti-c, anti-Fy^a, anti-C, anti-Jk^a, anti-S, anti-Jk^b.[128,129] All other clinically significant antibodies occur with an incidence of less than 1% of serum containing antibodies. Anti-P$_1$, anti-M, anti-N, anti-Lu^a (Lutheran), anti-Le^a, anti-Le^b, and anti-Sd^a are all considered clinically insignificant unless the alloantibodies are reactive in tests performed strictly at 37° C.[44,128] Clinically insignificant antibodies that react at 37°C by indirect antiglobulin test are those of the Knops and Ch/Rg systems and anti-JMH.[44,128] Other alloantibodies are clinically significant in some patients but not in others; examples are anti-Vel, anti-Ge (Gerbich), anti-Yt^a, and anti-Co^a (Colton).[44] Table 36-2 summarizes the clinical significance of antibodies to RBC blood group antigens.

The clinical significance of an antibody to a low-incidence antigen depends on whether it was found during crossmatching or prenatal testing. The specificity of a low-incidence antibody detected during compatibility testing need not be identified to locate antigen-negative blood with which to transfuse that patient because the full crossmatch will be positive in the rare event that a unit of donor blood from the stock supply carries the low-incidence antigen. In contrast, if an antibody to an uncommon antigen is detected in the serum of a pregnant woman, identification of the antibody, or determination of the antigen carried by the fetal or paternal RBCs, can be used as a predictor for the likelihood and severity of HDN. Blood for exchange transfusion will not be difficult to find.[44]

If a patient's serum contains alloantibodies to a high-incidence antigen, blood may be difficult to find. Examples are anti-U, anti-Kp^b, anti-Js^b, anti-Lu^b, and all antigens in the high series recognized by the ISBT Working Party.[74] Whether the investigation is for transfusion purposes or prediction of HDN, the antibody should be identified. This will aid in both the assessment of its clinical significance and the location of appropriate blood for transfusion.

Blood group antibodies in donor plasma present little hazard to an antigen-positive recipient or RBC units that have low plasma volumes. However, components that have significant plasma, such as fresh frozen plasma (FFP) or platelets, should generally be selected to lack ABO antibodies against recipient antigens. If platelets lacking ABO antibodies against the patient are unavailable, there is a small risk of a potentially severe reaction, and some blood banks have implemented procedures to minimize transfusion of incompatible isohemagglutinins. Donor blood is always tested for the presence of antibodies to antigens other than ABO and blood components containing such antibodies are generally not transfused to patients expressing the corresponding antigen.

Sera from some patients contain autoantibodies that recognize antigenic determinants on RBCs from the majority of individuals as well as their own. In such cases it may be impossible to locate compatible blood and only incompatible blood will be available. This may arise in such cases as autoimmune hemolytic anemia, cold agglutinin disease, and paroxysmal cold hemoglobinuria; these are discussed later in this chapter.[44]

Testing Donor Blood

Donor blood is routinely tested for its ABO and Rh blood group status. More extensive typings for other antigens are performed either when antigen-negative RBCs are required for a recipient whose serum contains clinically significant antibodies or when building an inventory of donors with certain antigenic profiles for future use, such as in the transfusion management of sickle cell disease (discussed later). The more alloantibodies are present, especially to high-frequency antigens, the longer the time needed to locate compatible units.

Compatibility Procedures

The routine approaches used involve testing a blood sample from a prospective recipient for ABO and Rh blood groups and for detection of blood group antibodies.[47] In most cases no unexpected antibodies are detected and donor RBCs of the appropriate ABO and Rh blood type will be selected for transfusion. A sample of this blood may be crossmatched with the patient's serum by an immediate spin procedure or an "electronic crossmatch" in which a validated computer system verifies that the patient is receiving an RBC unit that is ABO and Rh(D) compatible with the patient's blood group.

When an antibody is detected, an attempt should be made to identify its specificity. Knowing the specificity of an antibody allows the clinician to establish whether it is likely to be clinically significant and the approach that will be necessary to provide an adequate supply of compatible RBCs.

Compatibility in ABO and Rh

Determination of the ABO and Rh(D) type of the patient is the first step in compatibility testing. In neonates the ABO group is determined by testing the neonate's RBCs only because the plasma may contain maternal antibodies and young neonates' immune systems do not make isohemagglutinins. In patients older than 4 months, the ABO group is determined by testing both the patient's RBCs (forward group) and the plasma or serum (reverse group). The forward and reverse groups should correspond, except that infants younger than 9 months old may not yet make isohemagglutinins. In all other patients, until any discrepancy is resolved, only group O RBCs and AB plasma should be given.

Blood and blood components must be selected to be ABO and Rh compatible (Table 36-3). In general, for patients older than 4 months of age, type-specific RBCs and whole blood are selected, which means that donor and recipient have the same ABO and Rh type; it is acceptable to transfuse ABO and Rh compatible but not identical RBCs. For transfusions of a fetus, group O Rh(D−), irradiated, CMV antibody–negative or leukoreduced RBCs (or both) are usually given regardless of the ABO group of the recipient. For neonates some centers transfuse type-specific RBCs, whereas other centers transfuse group O RBCs to all infants. If the RBCs selected for transfusion are not group O, the neonate's serum or plasma should be tested for maternal anti-A or anti-B IgG antibodies in addition to IgM isohemagglutinins.[47] If anti-A or anti-B is detected, RBCs that are ABO-compatible with the antibodies should be transfused.[47]

Compatibility in Other Blood Groups

Compatibility testing for blood groups other than ABO is achieved by the antibody screen and crossmatch (Figs. 36-2 and 36-3). These tests detect unexpected RBC antibodies in the patient's serum. The patient's serum or plasma—or in the case of a neonate, maternal serum or plasma—may be used for the antibody screen.[47] In the antibody screen the patient's serum is mixed with group O reagent RBCs, which have most of the important blood group antigens. Because neonates are unlikely to produce new antibodies, the antibody screen must be performed only once per admission if the initial antibody screen is negative.[47] In the crossmatch the patient's serum is mixed with donor RBCs or "electronically" crossmatched using a validated computer system.[47] In patients older than 4

TABLE 36-3 Compatible Donors for Red Blood Cell Transfusion

Patients ABO/D	O Positive	O Negative	A Positive	A Negative	B Positive	B Negative	AB Positive	AB Negative
O positive	+	+						
O negative		+

AB positive	+	+	+	+	+	+	+	+
AB negative		+		+		+		+

months of age, the crossmatch is performed for every unit of RBCs or whole blood transfused. In neonates if the initial antibody screen is negative, it is unnecessary to crossmatch donor RBCs.[47]

If a blood group alloantibody is detected in the recipient's serum, every attempt should be made to identify the antibody. The clinical significance of an antibody is based on knowledge of the specificity of the alloantibody and the reported experience in other patients whose serum contains the same antibody specificity (see Table 36-2).[44] If the antibody has potential clinical significance, antigen-negative blood should be selected and crossmatched by a procedure that includes the antiglobulin phase.[37,47]

Selection of Blood for Transfusion to Patients with Blood Group Alloantibodies

Many alloantibodies detected in vitro in human sera do not have the potential to induce in vivo destruction of incompatible RBCs. No technical procedure is able to differentiate, with certainty, between clinically benign and clinically significant antibodies. Although the in vitro characteristics of an antibody may not reflect its behavior in vivo, the following features can be used to help establish its potential significance in a patient. In general, antibodies of the IgG class are more clinically significant than those of the IgM class.[44] Also, the higher the titer of an antibody, the more likely it is to destroy antigen-positive RBCs in vivo. An antibody that causes in vitro hemolysis owing to complement activation (see Table 36-2) of antigen-positive RBCs is likely to be clinically significant. Antibodies that react at 37° C are more likely to be clinically significant than those that do not.[44] For cold-reacting IgM antibodies, the wider the thermal range of reactivity in vitro, the more likely it is to be clinically significant. Alloantibodies that react in the cold and are not usually clinically significant include antibodies to M, N, P_1, Le^a, and Le^b antigens.[128] In difficult cases a few reference laboratories can also perform a monocyte monolayer assay that has some value in predicting whether an antibody will cause a hemolytic transfusion reaction.[130]

Once a patient is actively immunized to an RBC antigen and produces a clinically significant alloantibody, the patient is considered immunized for life and must be transfused with RBCs lacking the corresponding antigen for life. Neonates with passively acquired maternal

If a full crossmatch is performed, Coombs' reagent is added to the cells and serum and the cells are examined for agglutination.

antibody are not actively immunized and thus need to be transfused with antigen-negative RBCs only while the antibody is still present.

Emergency Need

When RBC transfusion is urgently needed in a rapidly bleeding patient, compatibility testing should be abbreviated so as not to delay transfusion. The clinician should indicate the need for emergency release of blood and send a pretransfusion patient blood sample to the blood bank. The blood bank can issue group O Rh(D–) RBCs and AB plasma or, if time permits, ABO type-specific RBCs. In some cases of inventory shortages, these patients, especially male ones, may receive Rh(D+) RBCs. In cases of emergency transfusion, the antibody screen and crossmatch may be performed after the blood has been transfused, and the clinician is notified of an incompatible crossmatch.[131]

Autologous Blood

Autologous blood transfusion is possible for some children who undergo elective surgery for which transfusion is anticipated. Transfusion of such blood reduces the risk of transfusion-transmitted viral diseases, but no blood transfusion is without risk. For example, autologous blood transfusions can be contaminated with bacteria or can cause volume overload, and there is always the risk of transfusing the incorrect unit. Intraoperative RBC salvage can be used if tumor cells or bacteria are not expected to contaminate the surgical field.

To donate autologous blood before surgery, a child must meet size or age requirements of the blood donor center, have adequate venous access, and have an Hb concentration of 11 g/dl or greater and a hematocrit of 33% or greater.[131] Some blood donor centers will collect small units that are proportional to the child's size. Donation should begin 4 to 5 weeks before surgery to allow time for in vivo RBC regeneration. Oral iron supplementation is often given. Recombinant erythropoietin is not routinely recommended for autologous blood donors and has not been licensed by the Food and Drug Administration for autologous donation, but it may be useful in certain circumstances.[132-135]

Directed Donations

Some institutions allow family and friends to direct their blood donations to be used for a child or infant. This is no safer than random banked blood and adds additional administrative expenses. GVHD can occur when the patient shares an HLA haplotype with an HLA homozygous blood donor, and this is more likely to occur if a patient receives blood from a relative.[28,29,136] Hence directed donations from blood relatives should be irradiated, and most institutions irradiate all blood donated by directed donors. Theoretically, blood from some female relatives has a higher chance of containing anti-HLA or antineutrophil antibodies that can contribute to transfusion-related acute lung injury (TRALI). Additionally, transfusion from a relative may induce antibodies to that relative's HLA antigens, complicating future donations of other tissues or organs from that relative.

Choice of Red Blood Cell Units for the Fetus

For intrauterine transfusions, group O Rh(D–) (and antigen-negative if mother has an alloantibody) RBCs should be used. To prevent graft-versus-fetus disease, blood is irradiated. To prevent CMV infection, CMV antibody–negative RBCs or leukocyte-reduced RBCs (or both) should be used.

Choice of Blood for the Neonate

Cellular components should be selected from CMV antibody–negative donors for neonate recipients weighing less than 1200 g at birth if their mother's are CMV antibody–negative.[137] Alternatively, leukocyte-reduced blood can also be used to prevent CMV infection if the blood product has less than 5×10^6 donor leukocytes.[138] Cellular blood components should be irradiated to prevent GVHD in these low-weight premature infants.[139]

In exchange transfusions for the neonate with HDN, RBCs used must be negative for the implicated antibody (e.g., Rh[D–] RBCs when hemolysis is caused by anti-Rh[D]). In terms of selection of ABO group, group O RBCs and plasma of the infant's ABO group are often used. Group-compatible RBCs and plasma can also be used if the RBCs are also compatible with any maternal antibodies that are present in the infant's circulation.[44]

TABLE 36-4 Approaches to Antigen Typing of Blood for Patients with Sickle Cell Disease

Approach	Advantages	Disadvantages
Treat like other patients (i.e., avoid antigens to which the patient has made antibodies)	Simple; avoids unnecessary work	Some patients will make antibodies that can result in serious transfusion reactions that may be especially dangerous in these patients Patients are probably at increased risk for the development of autoantibodies
Provide fully antigen-matched blood before the patient makes antibodies (i.e., matched for D, C, E, c, e, K, Fy^a, Fy^b, Jk^a, and Jk^b antigens). Note that antigen matching for Fy^b is not needed for patients of African descent who are Fy(a– b–) because they have the *FYB* gene, which is expressed in the lung and colon, and do not mount an immune response to the Fy^b antigen on transfusion of Fy(b+) RBCs	Reduces the risk of alloantibody and autoantibody formation and the risks associated with these antibodies	Significant work to reduce the risk for an antibody that may never develop; may be difficult to identify units with extended phenotype matches
Provide antigen-matched blood after the first antibody is made	Reduces the chance of multiple antibodies with less work than extended phenotype matching for all patients	Some patients will make multiple antibodies quickly
Provide partially antigen-matched blood (i.e., matched for D, C, E, and K antigens)	Reduces the chance of multiple antibodies with less work than extended phenotype matching that includes antigens that are not very immunogenic	Some patients will make antibodies against unmatched antigens

RBCs, Red blood cells.

Choice of Blood for Patients with Sickle Cell Anemia

Two important principles must be followed in the transfusion of patients with sickle cell anemia: (1) avoidance of excessive viscosity and (2) prevention of sensitization to RBC antigens.

Sickle cells are intrinsically less deformable than normal cells; thus elevating the hematocrit concentration without significantly reducing the proportion of sickle cells may raise the blood viscosity to dangerous levels.[140] Simple transfusion must be used with caution, particularly in children with hematocrit concentrations greater than 30%.

The question of what to use to transfuse patients with sickle cell anemia has been the subject of many heated debates.[141-143] There is still no consensus as to the best and most practical approach. Patients with sickle cell anemia, like all patients, are at risk for developing alloantibodies, and alloantibodies may pose specific hazards to patients with sickle cell disease. Patients with sickle cell disease usually need many transfusions throughout their lives, and an antibody to a blood group alloantigen that develops in childhood may be undetectable later in their lives. If they are then transfused with blood expressing that antigen, they are likely to develop an anamnestic response to the antigen and develop a delayed hemolytic transfusion reaction. Patients with sickle cell anemia have been reported to develop painful crises secondary to delayed hemolytic transfusion reactions. Additionally, a patient with sickle cell anemia who develops RBC alloantibodies may be at increased risk for the development of RBC autoantibodies that can significantly complicate the patient's disease.[143] For these reasons some transfusion services provide phenotype-matched blood for patients with sickle cell disease. Approaches that are used include those described in Table 36-4. Note that none of these approaches will prevent the production of antibodies to high-incidence antigens, such as U, Js^b, Cr^a, hr^S, and hr^B. African Americans tend to be null for antigens commonly expressed in the general donor population, which is mostly Caucasian in the United States. For this reason some blood donor facilities have programs to recruit African Americans to donate blood to support the transfusion needs of patients with sickle cell anemia. One potential risk of this approach is that patients are then likely to be exposed to many more Rh variant genes that are prevalent in the African-American population.

Thalassemia

In thalassemia the goals of transfusion therapy are the prevention of anemia and the maintenance of a circulating Hb level that is sufficient to suppress endogenous erythropoiesis. For most patients maintenance of a pretransfusion Hb level of 9 to 10 g/100 mL is sufficient.[144] RBC alloantibodies are not a significant problem in most patients with thalassemia, possibly because their transfusions are usually initiated at an early age when tolerance may develop or because they don't generally develop crises associated with hemolysis, as occurs in sickle cell disease. Therefore most institutions in the United States do not provide RBCs that are phenotypically matched to the patient's red cells.[145,146]

Choice of Blood for Allogeneic Hematopoietic Progenitor Cell Transplants

Because an HLA-identical donor is usually required for allogeneic hematopoietic progenitor cell (HPC) transplantation, the donor may not have the same ABO and

TABLE 36-5 Choice of Blood for Bone Marrow Transplant Patients

Recipient	Donor	Red Cells

O	AB	O

Rh type as the patient.[37] In major ABO incompatibility, the recipient has antibodies against donor RBCs (e.g., recipient is group O and has anti-A and anti-B; donor is group A). In minor ABO incompatibility, the donor has antibodies against recipient RBCs (e.g., donor is group O and has anti-A and anti-B; recipient is group A). These incompatibilities may produce hemolysis,[44] but hemolysis is often minimized by proper selection of blood products for transfusion.

In major ABO incompatibility (e.g., donor is group A, recipient is group O), host-versus-graft reactions can cause delayed erythropoiesis and even RBC aplasia.[147] To prevent recipient destruction of donor RBCs at the time of HPC infusion, donor RBCs are removed from the HPC before infusion. The group O recipient may continue to produce anti-A and anti-B after transplantation and cause hemolysis of the newly produced donor group A RBCs. If transfusions are necessary during this period, group O RBCs can be given (Table 36-5). Before transplantation the group O recipient has anti-A and anti-B. After engraftment of group A donor marrow, the anti-B will persist but the anti-A will become undetectable. Donor group A RBCs are given only after the recipient stops producing anti-A—that is, when the recipient's group O blood type changes to the donor group A and anti-A is not detected in the patient's serum.

In minor ABO incompatibility, hemolysis of recipient RBCs by donor antibody is usually preventable. To prevent hemolysis of recipient RBCs by passively transfused donor antibody during HPC infusion, plasma is removed from the HPC preparation before infusion. In addition, passenger B lymphocytes in the donor HPC may produce antibodies that may destroy recipient RBCs. To prevent hemolysis of transfused RBCs, group O RBCs are used for transfusions during the posttransplant period if the antibody is detected. If the donor or recipient has a clinically significant antibody to an erythrocyte antigen, blood lacking the antigen should be given after transplantation.[47]

Choice of Blood for Organ Transplantation

The ABO antigens are strong histocompatibility antigens and thus are of major importance in organ transplantation. Because the ABO antigens are expressed on the vascular endothelium, the recipient can reject and damage vascular endothelium of a donor organ that is a major ABO mismatch. For this reason, major ABO-incompatible vascular organ (liver, kidney, heart, lungs, pancreas) transplants are usually not performed. However, ABO-incompatible heart transplants may be performed in infants and young children who have not yet produced isohemagglutinins or who have produced only low levels of isohemagglutinins.[148]

When organ transplants are performed in the presence of minor ABO incompatibility, the same hemolytic problems as in HPC transplant may occur.[149] Passenger B lymphocytes may produce antibodies against recipient RBCs. Hemolysis of transfused RBCs can usually be prevented when an antibody is detected, by transfusion of group O RBCs for ABO incompatibility and transfusion of antigen-negative RBCs for incompatibility owing to other blood groups.

Selection of Blood for Transfusion to Patients with Blood Group Autoantibodies

Autoimmune hemolytic anemia is described in detail in Chapter 13. In hemolytic anemia resulting from warm-reactive autoantibodies, no compatible blood can usually be found. The direct antibody test ([DAT]; Fig. 36-4) will almost always be positive in autoimmune hemolytic anemia. Blood bank serologic testing is aimed at determining whether underlying clinically significant alloantibodies are present and identifying the specificity of any such antibodies that exist. This can be determined, with time, at a hospital transfusion service, which may require that the testing be performed at an immunohematology reference laboratory. Patients without a history of transfusion or pregnancy are unlikely to have underlying alloantibodies. Transfused RBC units should be compatible with any underlying clinically significant alloantibodies.

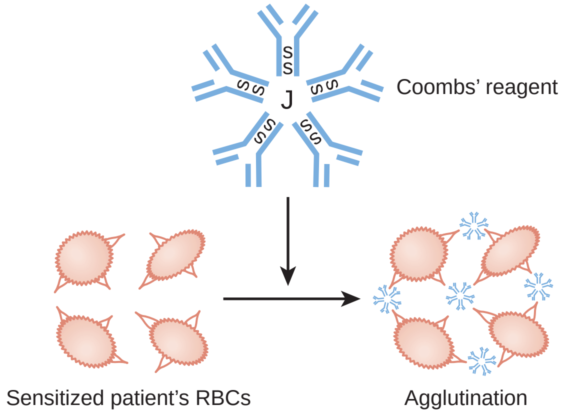

Figure 36-4 Direct antiglobulin test. Red blood cells *(RBCs)* are incubated with Coombs' reagent; if the cells agglutinate after incubation, the direct antiglobulin test is positive.

However, the blood is still usually incompatible with the patient's serum, and the clinically necessary amount of RBCs should be transfused with careful monitoring but without delay. In some patients the warm autoantibody has a clear-cut specificity for an antigen, and antigen-negative RBCs may be compatible in the crossmatch test.[150]

In paroxysmal cold hemoglobinuria associated with the Donath-Landsteiner antibody, transfusion is not usually necessary. The antibody binds RBCs only at cold temperatures (<20° C). In theory, it is reasonable to transfuse blood through a blood warmer; however, in practice crossmatch-compatible, unwarmed random RBCs have been given without problem.[151] Only rarely is transfusion of RBCs of the rare phenotype p needed.[152,153] Most cases of paroxysmal cold hemoglobinuria in children are transient and occur after viral infections.

In cold agglutinin disease, a rare condition in children, RBCs should be transfused through a blood warmer. As described previously, the same issue of testing for underlying alloantibodies pertains here.

Adverse Effects of Transfusion

All reactions other than mild allergic (urticarial) reactions require the immediate cessation of the transfusion and sending of a fresh blood sample from the patient to the blood bank for serologic evaluation.

Allergic Reactions

The typical urticarial reaction is characterized by itching and hives. Localized urticaria simply requires interrupting the transfusion and administering an antihistamine. If the symptoms resolve within 30 minutes the transfusion can be continued. Recurrent allergic reactions may require pretreatment with antihistamine.

Some children exhibit more severe allergic reactions, such as laryngospasm and bronchospasm. These patients may require steroids, epinephrine, or both (Table 36-6). The same unit of blood should not be restarted, even after symptoms have responded to treatment. Saline-washed blood products may be helpful in patients with severe or recurrent allergic reactions. Anaphylactic reactions may occur if the patient is IgA deficient and has formed an

TABLE 36-6 Guidelines for the Management of Transfusion Reactions

Agent	Use	Dose	Comment
Diphenhydramine	Treating pruritus and rash (hives)	6.25 to 25 mg IV over period of 10 to 20 min	Diphenhydramine cannot prevent and has no place in the treatment of severe transfusion reactions
Epinephrine	Severe reactions characterized by bronchospasm, hypotension, and shock	0.1-0.4 mg SC (or IV if the patient is hypotensive)	For patients in shock not responding to epinephrine, treatment with an initial fluid bolus should be initiated; as in patients with shock from other causes, fluids, vasopressors, airway protection, and oxygenation should also be used
1:20 Aqueous suspension of epinephrine	After stabilization with epinephrine	0.05-0.2 mg SC	
Fluids			For hypotensive patients, a bolus of 20 mL/kg of normal saline should be administered simultaneously with epinephrine and steroids
Narcotics	Specific and effective treatment of rigors	0.1 mg/kg of morphine IV (or equivalent dose of meperidine hydrochloride)	
Acetaminophen (Tylenol)	Prevention or reversal of elevations in temperature in mild to moderate febrile reactions	Appropriate for age	
Steroids	In moderate to severe reactions; may occasionally be required for severe urticaria; indicated in all reactions characterized by fever, shaking chills, diaphoresis, and pallor	1 to 2 mg/kg of methylprednisolone (or equivalent dose of dexamethasone or hydrocortisone by intravenous push)	

IV, Intravenously; *SC,* subcutaneously.

IgE anti-IgA antibody. In these cases, either washed blood products or products drawn from rare IgA-deficient donors are indicated.

Febrile Nonhemolytic Reactions

The occurrence of fever, chills, or diaphoresis usually results from cytokines and other pyrogens released from leukocytes and platelets.[154] Cytokines can be released from leukocytes during storage or on infusion to a patient who has antibodies that react with antigens on foreign white blood cells. Febrile nonhemolytic transfusion reactions are not associated with serious sequelae and may be treated with antipyretics. Of note, fever during a transfusion may represent another, more serious types of transfusion reaction: acute hemolysis, sepsis from a bacterially contaminated unit, or TRALI.

Acute Hemolytic Transfusion Reactions

Acute hemolytic transfusion reactions are most often the result of donor-recipient ABO incompatibility. These reactions are generally caused by managerial errors, such as the misidentification of a transfusion recipient.[155,156] The clinical presentation of acute hemolytic transfusion reactions varies. Signs and symptoms may include any or all of the following: fever, chills, dyspnea, tachycardia, hypotension, flank pain, abdominal pain, pain at the infusion site, apprehension, nausea, vomiting, and hemoglobinuria. Other serious sequelae may include acute renal failure, shock, and disseminated intravascular coagulation (DIC), which may present as bleeding. Some acute hemolytic reactions are characterized by only minor initial symptoms. In anesthetized recipients the only manifestations may be diffuse bleeding (owing to DIC) or red urine (hemoglobinuria). When an acute hemolytic transfusion reaction is suspected, the transfusion should be stopped immediately and an investigation should be initiated. The identity of the patient and unit should be reconfirmed. The remainder of the unit and a fresh blood sample should be sent to the blood bank, where the required workup includes the following: (1) a clerical check, (2) visual inspection of the recipient's plasma for hemolysis, and (3) a DAT. If there is no hemolysis in the patient's plasma or urine and the DAT result is negative, immune-mediated hemolysis can be excluded.

Therapy of an acute hemolytic reaction is supportive. Depending on the size of the child, a urine output of 40 to 100 mL/h should be maintained. Early consultation with nephrologists is warranted. Intravenous administration of furosemide or mannitol, which increases renal blood flow, may be required.

Delayed Hemolytic Transfusion Reactions

Delayed hemolytic transfusion reactions are of two different types: primary immunization and anamnestic response. Primary immunization is mild and occurs weeks after transfusion. It rarely causes significant hemolysis and may be suspected after an unexplained decrease in Hb level 2 to 3 weeks after transfusion.

Secondary immune responses occur in patients who have been sensitized to one or more non-ABO blood group antigens during a prior transfusion or pregnancy. When a patient is reexposed to the antigen, an anamnestic response occurs, resulting in a rapid rise in antibody level and accelerated clearance of the transfused antigen-positive RBCs. These patients experience some of the symptoms of a hemolytic reaction 3 to 10 days after transfusion. The clinical syndrome is usually mild, but delayed transfusion reactions can result in profound anemia. These reactions should be suspected in patients who have received multiple transfusions and develop unexplained anemia or bilirubinemia (or both) 3 to 10 days after transfusion. The diagnosis is confirmed by a positive DAT result and identification of RBC alloantibodies in the patient's serum or on the patient's RBCs (or both).

Transfusion-Associated Acute Lung Injury

TRALI presents with some combination of fever, chills, dyspnea, cyanosis, hypotension, and bilateral pulmonary infiltrates.[157,158] The reported incidence is 1 in 5000 transfusions but may be lower in pediatric patients.[159] Many cases appear to result at least in part from antibodies in donor plasma that react with patient HLA or neutrophil antigens. Blood banks minimized the use of plasma from female subjects that is most likely to contain such antibodies, resulting in a significant reduction in TRALI incidence. TRALI is often self-limited, with resolution in 48 to 96 hours in most patients who receive supportive care such as supplemental oxygen and often mechanical ventilation. However, in approximately 20% of patients TRALI can be severe and recovery prolonged; some cases, in fact, are fatal.

Transfusion-Associated Circulatory Overload

Because blood components have high oncotic pressure, transfusion-associated circulatory overload (TACO) may occur, resulting in pulmonary edema. This is mostly seen in adults, although very young children may also be at risk. TACO is treated with diuretics, phlebotomy, and supplemental oxygen.[160]

Transfusion-Associated Gut Injury

Several case series reports have found an association between RBC transfusions and the development of necrotizing enterocolitis (NEC) in premature neonates.[161,162] Although these studies suggest an association, they do not prove that NEC is caused by transfusion and not by some other factors that occur around the time of RBC transfusions.[163]

Transfusion-Transmitted Diseases

Because of improvements in both donor screening and product testing, blood products are currently extremely safe. But even though the risks of transfusion-transmitted disease have been greatly reduced, they have not been eliminated entirely. Currently, all blood donations in the United States are tested for the presence of human immunodeficiency virus 1 and 2 (HIV-1 and HIV-2), hepatitis B virus (HBV), hepatitis C virus (HCV), human T-cell lymphotropic virus 1 and 2 (HTLV-1 and HTLV-2), West Nile virus (WNV), and syphilis, and all blood donors are tested for Chagas disease at least once. The battery of tests performed includes a combination of serologic tests and nucleic acid tests (NATs) that taken together are exquisitely sensitive. However, very recent infections may be missed (so-called window-period donations). The risks listed in the subsequent sections and summarized in Table 36-7 are based on mathematical models estimating the number of infectious donors whose blood tests negative for a disease because they are in the window period.

TABLE 36-7 Estimated Risk of Transfusion-Transmitted Diseases

Agent	Number of Infections/Million Units
HIV	0.5
HCV	0.5
HBV	2 to 5
HTLV	0.5 to 4

HBV, Hepatitis B virus; *HCV,* hepatitis C virus; *HIV,* human immunodeficiency virus; *HTLV,* human T-cell lymphotropic virus.

Posttransfusion Hepatitis

Hepatitis B Virus. The estimated risk of posttransfusion HBV infection is presently 1 in 200,000 to 1 in 500,000 units transfused.[164] Acute HBV infection is symptomatic in approximately 50% of adults, and 5% to 10% of those infected become chronic carriers. In contrast, HBV infection acquired in early childhood is usually asymptomatic and leads to a chronic-carrier state in more than 70% of those infected.[165]

Hepatitis C Virus. With the routine use of NAT screening, the per-unit risk of HCV is currently estimated to be about 1 in 2,000,000.[164] Children who receive HCV-infected blood products have a 30% to 50% chance of spontaneously clearing their infection.[166] Most others become chronically infected. Approximately 20% of children who have been infected with HCV develop signs of cirrhosis after 18 years of age.[167,168]

Human Immunodeficiency Virus. All units are tested for HIV-1 and HIV-2 by immunoassay as well as by NAT. With NAT the window period for HIV has been reduced to approximately 10 days. The per-unit risk of HIV infection is currently estimated to be 1 in 2,000,000.[164]

Human T-Cell Lymphotrophic Virus. HTLV is the causative agent for both adult T-cell leukemia and endemic spastic myelopathy.[169,170] Most cases have been reported in residents of or emigrants from Japan, Africa, and the Caribbean region. The most comprehensive report of transfusion-transmitted HTLV indicated that 65% of patients who received whole blood or cellular products from HTLV antibody–positive donors seroconverted. Blood from all donations is tested for HTLV-1 and HTLV-2; the current per-unit risk is estimated to be 1 in 641,000.[171]

West Nile Virus. WNV is a flavivirus common in Africa, West Asia, and the Middle East. Approximately 20% of infected individuals will develop a febrile illness. Rarely, WNV infection causes an encephalitis syndrome; elderly and immunocompromised individuals are those primarily at risk. WNV has recently become established in North America. The vast majority of cases are transmitted by mosquito bites, but transfusion transmission does occur in rare cases. As with HIV and HCV, NAT has almost completely eliminated WNV from the U.S. blood supply.

Cytomegalovirus. CMV is carried in and transmitted by lymphocytes. In most patients transfusion-associated CMV infection causes no symptoms, although it may cause a mild mononucleosis-type illness 3 to 4 weeks after transfusion. Transfusion of CMV-containing blood products into an immunocompromised host with no serologic evidence of prior exposure to CMV can cause a lethal systemic infection. Patients at risk for severe CMV infection include bone marrow transplant patients, organ transplant candidates and recipients, and high-risk neonates. Therefore patients who have never been infected with CMV and have an inherited or acquired immunodeficiency state should receive CMV-negative or leukoreduced RBCs.[172]

Babesia. *Babesia* spp., especially *Babesia microti,* is responsible for more transfusion-transmitted infectious diseases than any other pathogen in the United States. Many infections are asymptomatic, but disease can occur, especially in immunocompromised patients such as premature infants and patients without functional spleens. Symptoms generally occur 1 to 9 weeks after infection and can include fever, headache, chills, sweats, myalgia, malaise, and hemolytic anemia; symptoms have progressed to death in at least 12 cases of transfusion-transmitted babesiosis in the USA.[173] Although transfusion-transmitted babesiosis predominantly occurs in the endemic areas of the northeast and upper midwest United States, it is not restricted to those regions because both blood donors and units of blood travel.

Bacteria (Platelet Units). Platelets are associated with the same range of infectious pathogens as any other blood component, but septic transfusion reactions, caused by bacterially contaminated units, comprise a unique risk of platelet transfusion. In contrast to all other blood components, which are stored either at 4° C or frozen, platelets are stored at room temperature. The reason is that if platelets are chilled before transfusion, they are cleared rapidly from the recipient's circulation.[174] Although room temperature storage dramatically improves platelet survival in vivo, it also tends to promote bacterial growth. Currently, bacteria can be cultured from approximately 1 in 5000 apheresis platelet units.[175] In the United States blood donor centers generally use culture methods to screen for bacteria in all platelet products, although alternative rapid testing methods are also available. Using current screening methods, the per-unit risk of a clinically apparent septic transfusion reaction is estimated to be 1 in 75,000 platelet transfusions.[164]

PLATELET TRANSFUSIONS

Indications for Transfusion

Bone Marrow Failure

Bone marrow failure resulting in thrombocytopenia is the major reason for patients to receive platelet transfusions. Iatrogenic induction of bone marrow failure, secondary to chemotherapy or irradiation, is the most common cause of bone marrow failure in all age groups. Patients with malignancies involving the bone marrow (e.g., leukemia, lymphoma, neuroblastoma, metastatic disease from solid tumors, myelofibrosis) may also require platelet support. The decreased marrow production in these diseases is caused by displacement of megakaryocytes with malignant elements. In some cases the tumor cells produce substances (e.g., tumor necrosis factor) that inhibit the growth of normal marrow cells. If there is no evidence of platelet dysfunction, patients usually do not experience active bleeding if the platelet count is greater than 10,000/mm^3 and have minimal risk for spontaneous life-threatening hemorrhage until the count is less than or equal to 5000/mm^3.[176-180] Although the bleeding rate is higher in patients undergoing pediatric oncology and bone marrow transplant procedures, the bleeding risk is not closely associated with the platelet count, and transfusion triggers of 10,000/mm^3 are still recommended for pediatric patients.[181] However, additional coagulation abnormalities, such as acquired or congenital platelet dysfunction, clotting protein deficiencies, and vascular or tissue defects, require more aggressive platelet support to decrease the risk of hemorrhage.

Patients with primary bone marrow failure caused by a defect such as Fanconi anemia or aplastic anemia will also be thrombocytopenic. However, platelets are usually withheld from these patients unless they are actively bleeding because they have a high rate of alloimmunization to HLA antigens, which in turn will significantly reduce the success of future transfusions and complicate bone marrow transplants. Studies conducted before the introduction of modern leukoreduction filters found that exposure of patients with aplastic anemia to more than five platelet donors results in a significant reduction in successful transplantation owing to rejection of the donor bone marrow.[182] Although it is unclear whether this finding applies to current leukoreduced platelets, if these patients do require treatment for bleeding, it is best to use irradiated, single-donor, leukoreduced platelets in an attempt to minimize sensitization. The decision to transfuse a patient who has been newly diagnosed with aplastic anemia should not be taken lightly because even a single exposure to transfused platelets may adversely affect long-term survival if bone marrow transplantation fails. Once the patient has become refractory to single-donor and HLA-matched platelets, family donors might also undergo plateletpheresis if the patient is *not* a candidate for bone marrow transplantation.

Platelet Destruction

Shortened platelet survival may result from immune-mediated destruction or nonimmune mechanisms, leading to accelerated platelet consumption (Table 36-8). In general, prophylactic platelet transfusions are contraindicated in these patients because the infused platelets are rapidly destroyed and thus a “safe” platelet count cannot be maintained. Therefore platelet transfusions are reserved for episodes of active bleeding or in preparation for surgical procedures.

TABLE 36-8 Platelet Alloantigen Phenotype and Frequency

Alloantigen System	Glycoprotein Location	Allelic Forms	Phenotypic Frequency
HPA-1 (P1^{A}, Zw)	GPIIIa Leu–Pro33	HPA-1a (P1^{A1})/ HPA-1b (P1^{A2})	72% a/a 26% a/b 2% b/b
HPA-2 (Ko, Sib)	GP1b Thr–Met145	HPA-2a (Ko^{b})/ HPA-2b (Ko^{a})	85% a/a 14% a/b 1% b/b
HPA-3 (Bak, Lek)	GPIIb Ile–Ser843	HPA-3a (Bak^{a})/ HPA-3b(Bak^{b})	37% a/a 48% b/b 15% b/b
HPA-4 (Pen, Yuk)	GPIIIa Arg–Gln143	HPA-4a (Pen^{a})/ HPA-4b(Pen^{b})	99% a/a <0.1% a/b <0.1% b/b
HPA-5 (Br, Hc, Zav)	GPIa Glu–Lys505	HPA-5a (Br^{b})/ HPA-5b (Br^{a})	80% a/a 19% a/b 1% b/b
HPA-6 (Ca, Tu)	GPIIIa Arg–Gln489	HPA-6a (Ca^{b})/ HPA-6b (Ca^{a})	99% a/a <1% a/b <1% b/b
HPA-7 (Mo)	GPIIIa Pro–Ala407	HPA-7a (Mo^{b})/ HPA-7b (Mo^{a})	99% a/a <1% a/b <1% b/b
HPA-8 (Sr^{a})	GPIIIa Arg–Cys636	HPA-8a (Sr^{b})/ HPA-8b (Sr^{a})	99% a/a <1% a/b <1% b/b

Nonimmune Mechanisms. Nonimmune mechanisms include the utilization of platelets in areas of endothelial damage, such as hemolytic-uremic syndrome (HUS), thrombotic thrombocytopenic purpura (TTP), or NEC. DIC results in decreased platelet life span owing to consumption of platelets and activated clotting factors, such as fibrinogen in the formation of microthrombi in association with sepsis, shock, acidosis, or severe head trauma. In these syndromes it is essential to assess the risk of bleeding in determining the need for transfusion. Infants with NEC are often transfused more aggressively because many demonstrate marked gastrointestinal blood loss and may have a preexisting central nervous system hemorrhage associated with prematurity. Similarly, patients with DIC are often given platelets even though their counts may not be less than 10,000/mm^3, owing to consumption of clotting factors and evidence of ongoing bleeding. Successful outcome for these patients depends on elimination of the underlying disease—for example, treating sepsis with antibiotics, restoration of organ perfusion in states of shock, or removal of necrotic tissue. Patients with large cavernous sinus hemangiomas

(Kasabach-Merritt syndrome) have localized consumption of platelets and clotting factors, resulting in a laboratory picture of DIC.[183-185] Until the lesion is removed or begins to involute, the platelet and clotting factor consumption will continue. These patients usually do not require transfusion for thrombocytopenia because the high rate of platelet turnover results in younger and more hemostatically effective platelets in circulation. Finally, in TTP and HUS, platelet infusions are withheld as long as possible because it is thought that the infused platelets would lead to further hemolysis and organ damage by contributing to the formation of microthrombi in areas of endothelial damage.[186]

Hypersplenism may result in poor platelet survival owing to trapping of platelets in the expanded splenic bed. A more complex clinical situation arises with acute or chronic liver disease.[187] Splenic pooling, DIC, and poor platelet production may all contribute to the thrombocytopenia of hepatic disease. The presence of portal hypertension and esophageal varices from cirrhosis may be an indication to consider platelet transfusion in the presence of gastrointestinal bleeding or when the platelet count falls below 20,000/mm^3.[188,189] Acquired platelet dysfunction is associated with both acute and chronic liver disease owing to decreased hepatic clearance of circulating fibrin degradation products. When platelet transfusion is required, splenomegaly may affect initial platelet recovery measured in the first hour after transfusion, but not platelet survival as determined by the platelet count 24 hours later.[188-191]

Immune-Mediated Thrombocytopenia. In immune thrombocytopenia antibodies bind to epitopes on platelet membranes resulting in rapid removal of the platelets from the circulation. These antibodies are either "self-reactive" autoantibodies or specific for alloantigens, polymorphic epitopes expressed on platelet membrane receptors. Alloantibodies cause thrombocytopenia in neonatal alloimmune thrombocytopenia and posttransfusion purpura (PTP), both of which are discussed later in this chapter. Alloantibodies responsible for poor response to platelet transfusion are discussed in the section on platelet refractory state.

Autoantibody-Mediated Thrombocytopenia. Autoantibody to platelets may be present in association with other diseases, such as systemic lupus erythematosus, Epstein-Barr virus infection, CMV infection, varicella virus infection, multiple sclerosis, diabetes, thyroid disease, and drug-induced autoantibody as seen with valproic acid. It may also be present without other disease associations, as in idiopathic thrombocytopenic purpura. In either setting there is rapid removal of antibody-coated platelets in the spleen and, to a lesser extent, in the liver. Immune complexes may nonspecifically adhere or bind by means of Fc receptors on the platelet surface. A particularly interesting example of the latter is the entity heparin-induced thrombocytopenia (HIT).[192] In this case patients exposed to heparin therapy produce antibodies directed to platelet factor 4 (PF4) bound to heparin. Immune complexes of PF4-heparin and antibody bind via Fc receptors to platelets, causing platelet activation and a prothrombotic state in which platelets are consumed. This may be a devastating complication of heparin therapy that may be suspected in patients who show falling platelet counts a few days after initiating heparin therapy. Platelet transfusions are generally contraindicated insofar as they may exacerbate the prothrombotic state.

In states that increase platelet turnover, the bone marrow responds by increasing megakaryocyte number, size, and ploidy. This, in turn, results in fresher platelets that are slightly larger in size and represent a younger population than normal owing to the rapid turnover of thrombocytes. Thus the bleeding time in patients with immune-mediated thrombocytopenia is shortened, relative to the absolute number of platelets, and such patients rarely experience major bleeding even though the platelet count may fall below 10,000/mm^3.[193] Autoantibodies that interfere with functional epitopes on platelet glycoprotein receptors, such as in acquired Glanzmann thrombasthenia, are a notable exception to this rule. In this setting patients present with bleeding even with platelet counts greater than 20,000/mm^3.

In patients with rapid consumption of platelets by autoantibody, platelet transfusions are generally not indicated unless there is evidence of bleeding, regardless of the platelet count. Central nervous system and gastrointestinal bleeding may be the presenting features of autoantibody-mediated thrombocytopenia and require immediate aggressive therapy, including platelet transfusion. Although the platelets are rapidly consumed, active bleeding may stop or decrease significantly. Platelet transfusions should be used judiciously in combination with therapy aimed at reducing autoantibody production and blocking reticuloendothelial cell clearance of antibody-coated cells. The therapy for immune-mediated thrombocytopenia is discussed elsewhere.

Alloantibody-Mediated Thrombocytopenia—Neonatal Alloimmune Thrombocytopenic Purpura. In neonatal alloimmune thrombocytopenic purpura (NATP), maternal antiplatelet alloantibody has crossed the placenta, resulting in thrombocytopenia in the fetus and neonate. Harrington and Sprague first reported the observation that pregnant women may become alloimmunized to antigens expressed on fetal platelets.[194] Even during the first pregnancy, maternal antiplatelet alloantibodies can cross the placenta and cause profound thrombocytopenia in the fetus and newborn. In North America the alloantibodies identified are most commonly directed against human platelet antigen 1a (HPA-1a, also known as PLA-1). A complete list of platelet alloantigens and their frequency in those populations that have been studied thus far are listed in Table 36-8. The presentation of thrombocytopenia in a healthy infant whose mother has a normal platelet count is often the result of maternal alloantibodies.

The diagnosis of NATP is made with the demonstration of antiplatelet antibody in maternal plasma, reactive with *paternal* platelets. Maternal plasma is also screened to rule out the presence of autoantibody. More than 50% of the platelet-specific alloantibodies in NATP are reactive with the HPA-1a epitope on glycoprotein IIIa.[195] Healthy infants may not bleed or develop petechiae until the platelet count drops below 20,000/mm^3. Reports suggest that immune response genes may also play a role in platelet alloimmunization.[196-198] On the basis of these studies, there appears to be an increased incidence of alloimmunization against HPA-1a in mothers positive for HLA-B8 and HLA-DR3.

The diagnosis of maternal alloimmunization is usually made after the birth of a mother's first thrombocytopenic infant. Women who are then identified as sensitized to a platelet-specific alloantigen should be monitored very closely throughout subsequent pregnancies. Intermittent screening of maternal serum should be performed similar to prenatal Coombs testing in women who are Rh negative. All women in the mother's family should also be evaluated before or during their pregnancies to determine whether they might also be at risk of alloimmunization. If a HPA-1a–negative woman is also HLA-DR3 (DRw52) positive, she has a greatly increased risk of alloimmunization even during her first pregnancy.[198-200]

To determine whether the infant is at risk for thrombocytopenia secondary to maternal alloantibody, it is advantageous to establish the platelet phenotype of the fetus early in pregnancy. As early as the eighth week of gestation, DNA from nucleated cells obtained from chorionic villus sampling can be amplified through the use of the polymerase chain reaction. DNA typing is then determined with glycoprotein-specific oligonucleotide primers and probes unique for each alloantigen sequence or phenotype.[200-202] Results from a prospective study described a 100% correlation between DNA typing and subsequent serologic response in mothers with alloantibodies to PlA1 or Bak.[203] This technique is useful only where the nucleotide sequences that define the polymorphisms are known (see Table 36-8).[201]

Because of the high frequency of these alloantigens, random donor platelets are usually ineffective in treating alloimmune thrombocytopenia in the neonate. When platelets are given, it is best to use platelets lacking the implicated antigen. If the antigen is unknown or antigen-negative platelets are unavailable, then washed, irradiated *maternal* apheresis platelets can be used because they lack the alloantigen. Washing is required to remove maternal plasma that contains the alloantibody. *Irradiation is routinely performed on all blood products from first-degree relatives where there is an increased risk of GVHD, particularly in neonates*. When severe thrombocytopenia in the newborn is anticipated, antigen-negative platelets may be procured before elective delivery and made available for transfusion shortly after birth for infants with NATP diagnosed prenatally. Intravenous immunoglobulin has also been used successfully in the newborn.[204-208] In families with no history of prenatal intracranial hemorrhage, fetal platelet count should be closely monitored and ultrasonography performed to rule out bleeding before delivery.[209]

Platelet Transfusions for Surgery

Retrospective data suggest that a platelet count above 50,000/mm^3 is acceptable for a patient to undergo major surgery.[210] Certain circumstances may warrant more aggressive correction of thrombocytopenia before or after surgery. In areas where even a small amount of bleeding might cause permanent deficits, such as the eye or central nervous system, it is traditional to aim for a platelet count higher than 100,000/mm^3. During prolonged procedures where the patient will be on cardiopulmonary bypass or extracorporeal membrane oxygenation (ECMO), platelets may be dysfunctional owing to activation after passage through extracorporeal perfusion equipment. In general, there is no need to administer platelets to patients after extracorporeal circulation if there is no evidence of bleeding and the platelet count is at least 50,000/mm^3.[211-213] When bleeding is present, it is more commonly caused by heparin, inadequate protamine correction, fibrinolysis, or problems with surgical closure.

Minor procedures such as liver biopsies have been performed safely with platelet counts greater than 25,000/mm^3.[188] Similarly, lumbar puncture has been shown to be safe in the setting of thrombocytopenia. Howard and colleagues[214] reported a series of 956 consecutive pediatric patients with newly diagnosed acute lymphoblastic leukemia who underwent lumbar puncture. No serious bleeding complications occurred in 5223 lumbar punctures, including 170 procedures performed when the platelet count was 11,000 to 20,000/μL. The authors concluded that prophylactic platelet transfusion was unnecessary in patients with platelet counts above 10,000/μL. These procedures were performed in only 29 patients with platelet counts below 10,000/μL, so it was not possible to assess with confidence the risk of bleeding in patients with extremely low platelet counts.

Platelet Transfusions for Patients with Dysfunctional Platelets

Patients with congenital platelet dysfunction, such as Glanzmann thrombocytopathy or Bernard-Soulier syndrome, may experience episodes of profuse bleeding. In this setting platelets may be administered to control massive hemorrhage. Because normal platelets express proteins that these individuals lack, some patients develop isoantibodies to these receptors and eventually become refractory to all platelet transfusions. Efforts to minimize menstrual bleeding using hormonal suppression may decrease the number of platelet infusions in women. Bleeding in patients with congenital platelet dysfunction caused by abnormal platelet secretion may respond to desmopressin, avoiding exposure to blood.[215,216]

Acquired platelet dysfunction in children is most commonly caused by drugs, chronic renal failure, or antiplatelet antibodies. Rarely, children present with platelet dysfunction as a manifestation of myelodysplastic syndrome or chronic leukemia. Platelet transfusions may be used if the patient is actively bleeding, but eventually the transfused platelets will be affected by exposure to drug, uremia, or antiplatelet antibodies, which limit their survival and function. For this reason platelets are not given prophylactically in these patients. Every effort should be made to ameliorate the platelet dysfunction so that exposure to blood product is avoided. Patients with uremia may respond to infusions of desmopressin, and those with antiplatelet autoantibodies may respond to immunoglobulin infusions or corticosteroid therapy. When possible, alternative medications should replace those known to cause platelet dysfunction.

Platelet Units

Platelets are prepared for transfusion from a single unit of freshly collected whole blood (whole blood–derived [WBD] platelets) or from apheresis by means of continuous-flow centrifugation (apheresis platelets). Regardless of the technique used, platelets must always be collected and stored at 20 to 24° C and in anticoagulant-containing citrate-phosphate-dextrose (CPD) or CPDA-1 or an additive solution that may contain some combination of acetate, magnesium, potassium, or gluconate. Citrate anticoagulates the blood by binding plasma calcium, whereas dextrose is a nutrient source for actively metabolizing platelets.

Whole Blood–Derived Platelets

In the United States WBD platelets are prepared from whole blood by the platelet-rich plasma (PRP) method. PRP is separated from packed RBCs by centrifugation of whole blood ("soft spin"). The PRP is then centrifuged again ("hard spin"). All but 50 to 70 mL of the platelet-poor plasma (PPP) is transferred to an adjoining bag to be used for the production of fresh frozen plasma or other blood components, such as cryoprecipitate or albumin. When optimal centrifugation techniques are used, approximately 85% of the platelets (5 to 7 × 10^{10} platelets) are recovered from a unit of whole blood.[217-219] In Canada and Europe the alternate "buffy coat" method is used to generate platelet concentrates from whole blood.

Apheresis Platelets

Apheresis platelets from one individual should yield more than 3 × 10^{11} platelets in 200 to 300 mL of plasma. Modern apheresis equipment is often able to yield more than 6.5 × 10^{11} platelets per procedure and typically incorporates a leukoreduction step that leaves fewer than 1 × 10^{6} leukocytes per product. This allows units to be split into two or even three apheresis platelet units, each with five to six WBD platelet equivalents.[220,221]

Once they are processed, platelet units are stored on elliptical, circular, or flat-bed agitators.[222,223] This constant mild agitation prevents platelet clumping or activation as platelets settle to the bottom of the bag.[224,225] Constant agitation also facilitates gas exchange, which is important for maintaining an optimal pH range for platelet metabolism and function at 20°C.[226] Because of the risk of bacterial growth associated with room temperature storage, platelet units are usually stored for no more than 5 days.

Platelet Dosing

Guidelines for determining platelet dose have been published in a number of reviews.[227-229] In general, one unit of random donor platelets (5 to 7 × 10^{10} platelets) per 12 kg of body weight should increase the platelet count by 40,000 to 50,000/mm^3 within 1 hour after the infusion. In the average-size adolescent or adult, 6 units of platelet concentrate, or 1 single-donor apheresis unit (3 to 5 × 10^{11}), will increase the platelet count by 50,000/mm^3 or greater. This dose or a lower dose are equivalent in bleeding outcomes, whereas a higher dose increases the number of platelets transfused without any benefit in bleeding outcomes.[181,230] Concentrating or washing the platelets can result in variable platelet loss and decrease the platelet count increments after transfusion.

To determine the effectiveness of platelet transfusion, a platelet count should be obtained before infusion, at 1 hour, and at 24 hours after infusion. There is no significant difference in the posttransfusion platelet count when measured at 10 minutes versus 60 minutes after transfusion.[231]

Platelet Refractory State

When a patient no longer achieves the expected rise in platelet count after a platelet transfusion, the clinician must first assess whether the shortened platelet recovery and survival result from immune or nonimmune mechanisms. Examples of nonimmune mechanisms are listed in Table 36-8 and are responsible for the majority of cases in which posttransfusion count increments are lower than expected. The most notable of these include splenomegaly, DIC, and fever.

Normally, one third of the platelets released into circulation from the bone marrow are stored in the spleen. Hypersplenism causes a larger percentage of transfused platelets to be sequestered in the spleen. Hypersplenism results in a decrease in the platelet recovery immediately after platelet infusion but does not have an effect on platelet survival once a steady state has been achieved.[191]

Fever may reduce platelet recovery by 20% to 40%.[232,233] In one study decreased platelet recovery was documented in patients who underwent bone marrow transplant with fever and negative blood cultures. Although occult infection cannot be ruled out, in these patients fever alone was the only change associated with poor platelet increment.[233]

Consumptive coagulopathy (DIC) refers to the excessive activation of thrombin resulting in an accelerated conversion of fibrinogen to fibrin. This process may be acute and accompanied by rapid consumption of procoagulant factors and platelets in association with extensive bleeding, as in sepsis, shock, or certain forms of malignancy.[187,234] A chronic form of DIC may occur if the procoagulant consumption is slow enough for the liver to compensate for a limited consumption, as found in hemangiomas and necrotic lesion in the lung or brain, for example. In either form of DIC, recovery and survival of transfused platelets is shortened.[183-185] Diseases associated with primary endothelial cell damage, such as HUS and TTP, are also associated with a decreased platelet recovery owing to the formation of microaggregates in the areas of vascular damage.[186] Additional bleeding may be seen with these syndromes because of the acquired platelet dysfunction associated with renal failure and uremia.[190,228]

Older platelets may not remain in circulation as long as freshly collected platelet concentrates because of excessive activation during storage or metabolic effects of acidosis.[226] Platelets also express small amounts of ABO antigens, making ABO-incompatible transfusions slightly less effective than ABO-matched transfusions. Finally, analysis of multiply transfused patients show that there is a tendency to decreased average count increments with successive transfusions. A patient's first platelet transfusion may result in a 30% higher count increment than their fifteenth, despite equal numbers of platelets being transfused and in the absence of other factors. No definitive cause of this decrease has been discerned, other than the hypothesis that patients subjected to multiple rounds of chemotherapy may sustain subtle endothelial damage that consumes transfused platelets.[235]

To compare the effectiveness of platelet transfusion on different occasions or with different donors and recipients, the best ratio to use is the corrected count increment (CCI):

$$\mathrm{CCI} = \frac{\begin{array}{c}(\text{Posttransfusion count} - \text{Pretransfusion count})\\ (\text{body surface area m}^2)\end{array}}{\text{Number of platelets given } (\times 10^{11})}$$

Using this equation, the clinician can correct for the variations in number of platelets infused and for differences in patient size.[228,229] For example, if the platelet count is increased from 5000 to 65,000/mm^3 after a transfusion of 3×10^{11} platelets in a child with a body surface area of 1.2 m^2,

$$\mathrm{CCI} = 60{,}000 \times 1.2 / 3 = 24{,}000$$

This formula is most commonly used to define platelet refractoriness (CCI <5000 at 1 hour), but it has limited use to compare single tranfusions directly, insofar as it does not factor in the many other factors that may affect platelet count increments, as outlined in the preceding sections (Table 36-9).

Alloimmune Mechanisms

Alloimmunization is characterized by increasingly poor recovery and survival of platelets in the multiply transfused patient. The majority of alloantibodies react to determinants on HLA class I molecules and platelet-specific antigens expressed primarily on membrane glycoproteins.[236] The production of antiplatelet alloantibodies is weakly associated with the number of exposures or transfusions. However, there is an association with underlying disease state. For example, only 30% to 60% of patients with leukemia become alloimmunized, in contrast to 80% to 90% of aplastic anemia patients.[237,238]

Unlike the process for RBCs, it is not practical or efficient to crossmatch platelet donors and recipients in most blood centers or hospitals. The antigens known to elicit an immune response on platelets are allelic molecules. These include a variety of class I HLA alloantigens, platelet-specific alloepitopes such as HPA-1a, and blood group antigens. It is not reasonable to match all donors and recipients for HLA or platelet-specific alloantigen antigens. As seen in Table 36-9, the platelet-specific alloepitopes are diallelic with a high frequency of expression of one allele in the general population. Therefore the incidence of alloimmunization to platelet-specific antigens after a single transfusion may be a serious problem for only a very small percentage of the population depending on which epitope is involved.[229,238] An algorithm for dealing with patients who appear to be refractory to platelet transfusions is shown in Figure 36-5.

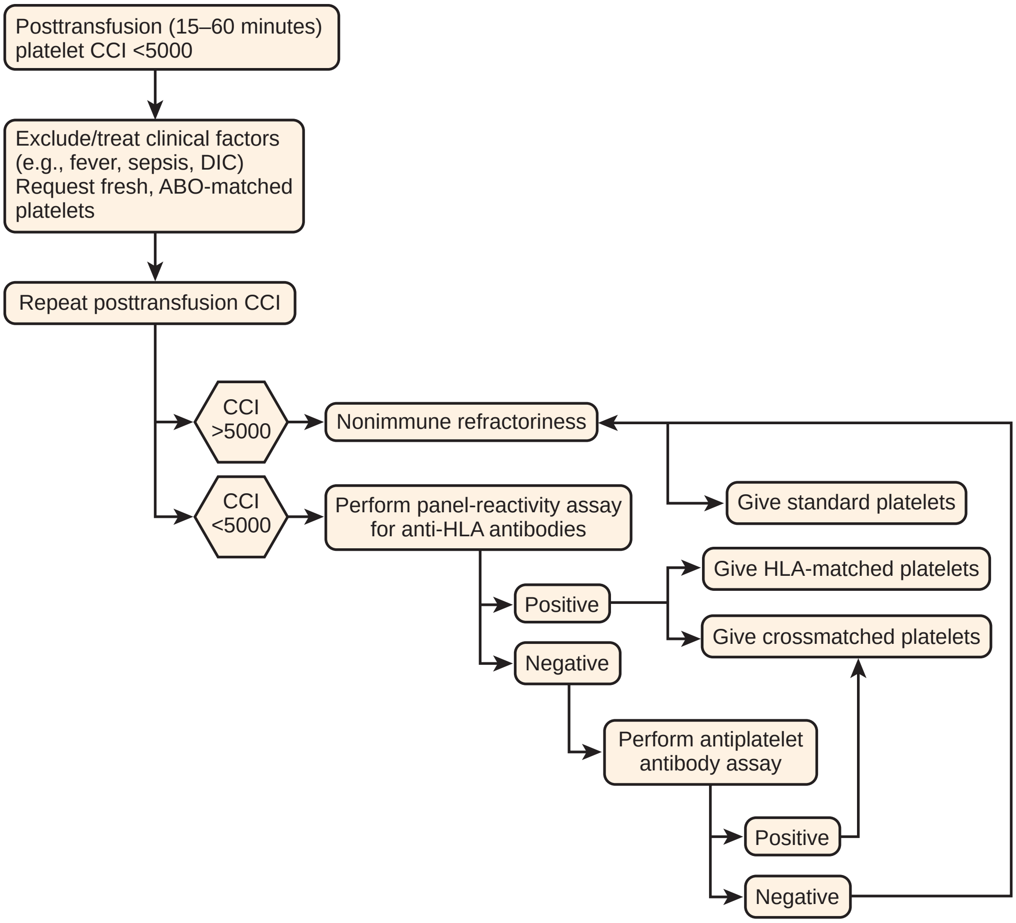
TABLE 36-9 Variables Resulting in Decreased Post-Transfusion Platelet Counts

Platelet Component	Clinical Condition
Donor platelet count	Fever
Technique of platelet collection	Sepsis
Temperature of storage	Amphotericin B therapy
Platelet component age	DIC
Storage conditions	Hepatosplenomegaly
Infusion time	Alloantibodies
Blood filter type	Autoantibodies
Leukocyte removal	Massive blood loss
Reducing platelet plasma volume	HUS
Washing platelets	TTP
ABO match	Necrotizing enterocolitis Multiple previous platelet transfusions

DIC, Disseminated intravascular coagulation; *HUS*, hemolytic-uremic syndrome; *TTP*, thrombotic thrombocytopenic purpura.

The majority of alloantibodies that mediate the rapid clearance of transfused platelets in the refractory patient bind to epitopes on class I HLA molecules. Platelets express the class I (HLA-A, -B, and -C) gene products,[239] but the class II molecules (HLA-DR, -DP, -DQ) have been shown only on platelets in a high turnover state, such as immune thrombocytopenic purpura, in which the majority of circulating platelets have just been released from the bone marrow.[240] As with other precursor cells, early megakaryoblasts express HLA-DR in normal individuals[241,242]; however, this antigen is generally not detectable on circulating platelets.

Initially, class I HLA alloantigens were defined serologically—that is, with plasma from patients or postpartum women with high-titer alloantibodies. Subsequently, molecular typing and monoclonal antibodies helped clarify the number and types of epitopes associated with the HLA-A, HLA-B, and HLA-C loci. Interestingly, it is the serologic definitions that are important in platelet refractoriness. In categorizing the alloantigens serologically, it became clear that two categories of epitopes were expressed. The first group of alloantibodies recognizes private epitopes, those antigens that are uniquely associated with only one HLA gene product. The second category contains alloantibodies that recognize public epitopes, which are expressed on more than one class I HLA gene product. The broad reactivity associated with the platelet refractory state is most commonly caused by alloantibodies that recognize *public* epitopes



Posttransfusion (15–60 minutes) platelet CCI <5000
Exclude/treat clinical factors (e.g., fever, sepsis, DIC) Request fresh, ABO-matched platelets
Repeat posttransfusion CCI
CCI >5000
Nonimmune refractoriness
CCI <5000
Perform panel-reactivity assay for anti-HLA antibodies
Give standard platelets
Give HLA-matched platelets
Positive
Give crossmatched platelets
Negative
Perform antiplatelet antibody assay
Positive
Negative

shared by many HLA gene products.[243,244] By categorizing HLA-A and HLA-B loci according to these public epitopes or cross-reactive groups (CREGs), blood banks may be able to provide single-donor platelets based on reactivity to CREG subsets. Blood banks take advantage of this observation to provide "HLA-compatible" platelets (type B matches) when HLA-identical donors are limited in number.[245] Although the platelets may not be identical at the HLA-A or HLA-B loci, if the CREGs shared by a subset of class I allotypes can be avoided, then non-HLA identical product can still be used, often with adequate platelet recovery and survival. Using this system, blood centers can expand their pool of volunteers providing single-donor platelets for multiply transfused patients; however, it remains difficult to provide fully HLA-matched platelets consistently. Because of this, the overall success rate for attaining suitable posttransfusion count increments with HLA-matched platelets is only approximately 50% in alloimmunized patients, even in major centers.[245]

Preventing Platelet Alloantibodies

Leukoreduction of platelet and RBC units for patients who are expected to require multiple platelet transfusions significantly reduces the rate of development of platelet alloantibodies. Although platelets express class I gene products, it is the class II molecules expressed on contaminating leukocytes that are primarily responsible for the induction of alloantibodies.[246,247] With the use of washed platelets devoid of white cells, multiply transfused animals failed to develop lymphocytotoxic antibodies.[248,249] These studies were eventually repeated in patients comparing pooled random-donor platelets with or without leukocyte depletion. At least 90% of the contaminating leukocytes had to be removed (less than 10^6 remaining), but there was a striking decrease in the rate of alloimmunization from 93% to 24%.[250-254] Prospective studies in humans suggest that the leukocyte threshold for alloimmunization is less than or equal to 5×10^6 cells per infusion. As outlined previously, the TRAP study[255] has conclusively demonstrated in a randomized, prospective study that the use of leukocyte-reduced products can effectively reduce, but not eliminate, the risk of alloimmunization. Most centers recommend leukoreduction in the blood center during collection,[256] which may also decrease the accumulation of cytokines produced by white cells during storage.[257,258]

PTP occurs 7 to 10 days after blood product infusion in a patient who has been previously transfused or pregnant.[259] Paradoxically, alloantibodies are produced that destroy not only any transfused platelets but also the patient's own platelets. Although extremely rare, PTP occurs most commonly in the less than 2% of the population who are HPA-1a negative.[195] The posttransfusion plasma usually has high-titer anti-HPA1a activity, but the mechanism of autologous platelet destruction is unclear. Hypotheses suggesting that there is a cross-reactive alloantibody that binds to autoepitopes in close proximity to the HPA-1a site have yet to be proved. There are individual cases reported of PTP secondary to alloantibody to Bak^a, Pen^a, and two cases of anti–HPA-1b antibodies.[260-262] Of the approximately 100 cases reported since its description in 1959, only four men have been described as having PTP.[195] A series of PTP patients with anti–HPA-1a alloantibodies were HLA typed and more than 90% were HLA-DR3 positive, with the supertype HLA-DRw52 predominating in these individuals.[197,198] Patients are usually in their late forties or older, but PTP has been reported in a 16-year-old girl not previously pregnant.[262]

Platelet transfusions are contraindicated in PTP patients in whom the treatment of choice is intravenous immunoglobulin, plasmapheresis, or both.[263] The frequency of transfusion reaction in these patients is quite high, with 46% experiencing chills and fever during blood product infusion. Therefore RBCs should be washed and filtered whenever possible. If platelets must be given for life-threatening hemorrhage, they should be HPA-1a negative, washed, and leukoreduced. Further discussion of therapy and possible mechanisms of autologous platelet destruction in PTP are more thoroughly addressed in two extensive reviews of this disorder.[201,259]

GRANULOCYTE TRANSFUSIONS

Granulocytes are available from some blood banks and blood centers. Three groups of patients may benefit from granulocyte transfusions. One group consists of neutropenic patients with a bacterial or fungal infection whose bone marrow is likely to recover. This group consists predominantly of patients who have undergone bone marrow transplant and patients who have received chemotherapy. The other groups that may benefit from granulocyte transfusions include neonates with sepsis and septic patients with dysfunctional granulocytes, such as patients with CGD. If there is a benefit, it is likely only for patients with a high risk of mortality receiving a relatively high dose of granulocytes.[264,265] Additionally, granulocyte transfusions are associated with adverse effects, including fevers and pulmonary complications, and high rates of alloimmunization to HLA antigens, a potentially serious complication for patients who may be candidates for bone marrow transplantion.[266] Granulocyte transfusions to patients at risk of CMV disease should be collected only from CMV-seronegative donors because granulocytes from CMV-seropositive donors contain the virus. Granulocyte transfusions should be closely coordinated with the blood bank and should be transfused as soon as possible after collection and no more than 24 hours after collection.

PRINCIPLES OF HEMATOPOIETIC CELLULAR THERAPY

With the advancement of molecular technology, a better understanding of human immunology, and the increased interest in regenerative medicine, the use of cellular therapy is no longer limited to hematopoietic stem cell transplantation (HSCT). Current applications have expanded to include the use of cells as adoptive immunotherapy and cancer vaccines. Future applications may also include the use of cells as a drug-delivery vehicle or as a source of tissue engineering for regenerative medicine.[267] However, HSCT is still the best-established type of hematopoietic-based cellular therapy. In this section the sources and processing of hematopoietic cell-based therapy and complications associated with its use will be reviewed.

Hematopoietic Cell Sources

The donors of therapeutic hematopoietic cells can be autologous or allogeneic. Autologous donors are usually patients who will be undergoing HSCT. These donors have their own cells collected and cryopreserved and have their own cells infused during transplantation. Because the donor and recipient are the same, complications caused by major histocompatibility complex (MHC) or HLA disparities are negligible for autologous cell infusions. The MHC/HLA molecules are displayed on cell surfaces and responsible for lymphocyte recognition and "antigen presentation." They control the immune responses through recognition of "self" and "nonself" and consequently serve as targets in transplantation. However, during allogeneic transplantation, the degree of HLA disparity is extremely important for donor selection because large numbers of lymphocytes are transfused. These donor lymphocytes can recognize recipient's tissue as foreign or "nonself" and mediate GVHD. HLA molecules are located on chromosome 6. There are two classes of HLA antigens, class I and class II. Class I antigens such as HLA-A and -B and class II antigen HLA-DR are the three most important molecules contributing to GVHD. Given that each person has two alleles of chromosomes, a minimum of six out of six HLA antigens matching is often required for transplantation. The donors for allogeneic hematopoietic stem cells are often siblings of the recipients and referred to as *related donors*. For patients who do not have related donors, cells from HLA-matched unrelated donors are frequently used. These donors are obtained from international donor registries such as National Marrow Donor Program (NMDP), and the amount of time spent searching for appropriate and available donors can be unpredictable. Because only 50% to 60% of patients have an HLA-matched sibling or an unrelated donor, not all patients who may benefit from HSCT can proceed to transplant. Timely search for an appropriate donor is essential for successful allogeneic HSCT.[268] A prolonged donor-search period can lead to death, increased risk, or ineligibility of the patients. The incidence of GVHD is also significantly increased when HSCT is performed with unrelated donors.[269,270]

TABLE 36-10 Differences in Transplanted Cell Dose and Hematopoietic Recovery Between Cell Sources

	Total Cell Dose Transplanted		Days to Hematopoietic Recovery	
Hematopoietic Stem Cell Source	Mononuclear Cells/kg ($\times 10^8$)	CD34$^+$ Cells/kg ($\times 10^6$)	Neutrophil	Platelets
G-CSF–stimulated peripheral blood	9.6 ± 6.1	9.3 ± 7.0	13 ± 4	17 ± 15
Bone marrow	2.6 ± 1.5	1.8 ± 1.2	19 ± 5	23 ± 12
UCB	0.44 ± 0.12	0.23 ± 0.14	29 ± 16	52 ± 23

From Dana-Farber Cancer Institute adult hematopoietic stem cell data, 2005.
G-CSF, Granulocyte colony-stimulating factor; *UCB,* umbilical cord blood.

Bone marrow, stimulated peripheral blood, and umbilical cord blood (UCB) are the sources of hematopoietic stem cells for transplantations. Unstimulated peripheral blood cells are used either in an unmanipulated state or can be further processed to be used as adoptive immunotherapy. Characteristic differences between various hematopoietic cell sources will be discussed individually.

HSCT can be performed with unmanipulated bone marrow, peripheral blood, or cord blood. The original HSCTs were performed using bone marrow. In recent years investigators have routinely used mobilized peripheral blood for transplantation[271-273] because of the higher number of CD34+ hematopoietic stem cell content and faster posttransplant hematopoietic recovery (Table 36-10). CD34+ cells are typically used as a marker for hematopoietic stem cells, and although CD34+ cell numbers are a good marker to predict the success of engraftment, some hematopoietic stem cells are actually CD34–.[273a] Depending on the source of cellular products used, they can be contaminated with different degrees of RBCs and leukocytes. Compared to peripheral blood–derived hematopoietic stem cells, bone marrow products have higher RBC contamination and lower numbers of T cells and CD34+ cells. Overall clinical outcomes of transplants from the two sources are equivalent.[274]

Mobilized peripheral blood collected by leukapheresis has become the most commonly used hematopoietic progenitor cell component for both autologous and allogeneic HSCT because of the ease of collection and ample number of CD34+ stem cells.[275] Peripheral-blood donors recover more quickly from pain related to the collection than do bone marrow donors.[276] Additionally, compared with autologous bone marrow transplants, autologous peripheral blood transplants result in more rapid engraftment, decreased need for transfusions, and decreased incidence of infection and antibiotic usage, as well as shorter hospital stay.[277] To mobilize stem cells into the peripheral blood, patients are treated with cytokines such as granulocyte-colony stimulating factor (G-CSF), possibly in combination with plerixafor, an inhibitor of the interaction between CXCR4 and CXCL12 that helps maintain stem cells in the hematopoietic microenvironment. Autologous donors are often mobilized after receiving chemotherapy that also contributes to the mobilization. The cells are usually collected in the outpatient setting. After chemotherapy the patient will undergo leukapheresis at the time his or her cell counts recover from the nadir. Circulating peripheral blood CD34+ cell levels may be used to predict yield.[278,279] If cytokines are used without prior chemotherapy, collection is begun on a predetermined day during the course of administration. Approximately 10% of autologous peripheral blood stem cell donors cannot be mobilized successfully with G-CSF alone, but approximately three fourths of these patients can be successfully mobilized with the addition of plerixafor.[280,281] The risk factors for poor mobilization include the patient's disease status and marrow environment related to history of heavy chemotherapy and radiation therapy.[282-285] Patients who fail mobilization with any agent are at increased risk of delayed engraftment, and non-transplant treatments or transplants of hematopoietic progenitor cells directly collected from the bone marrow are often considered.

If peripheral blood collections are used for allogeneic transplantation, collection is begun on the fourth or fifth day of G-CSF administration. As in the autologous setting, engraftment may be more rapid with allogeneic peripheral blood compared with bone marrow. However, peripheral blood components typically contain at least one log more T cells than bone marrow components, potentially increasing the risk for GVHD. Nevertheless, the incidence of acute GVHD is only moderately elevated, and the overall survival rate is equivalent.[286] This may in part result from effects of the G-CSF used for mobilization on the T cells. However, reports have suggested that chronic GVHD may be more frequent in recipients of peripheral blood components.[287] But peripheral blood transplants have less graft failure and equivalent overall survival rates compared with bone marrow transplants.[274]

The biology of CD34+ stem cell mobilization is now better understood. The bone marrow environment heavily regulates the movements of these CD34+ hematopoietic progenitor stem cells. Cytokines such as G-CSF stimulate the generation of granulocytes in both bone marrow and peripheral blood.[288,289] These granulocytes release serum proteases such as cathepsin G and neutrophil elastase. According to some reports, the accumulation of these serum proteases coincides with the increased inhibition of adhesion molecule interaction between the very late antigen 4 (VLA-4) on the CD34+ hematopoietic stem cells and the vascular cell adhesion molecule 1 (VCAM-1) on the surface of bone marrow stromal cells.[290] This adhesion molecule disruption allows the CD34+ hematopoietic progenitor cells to be free floating within the bone marrow environment, and their movement can then be influenced by chemokines. Interestingly, proteolysis of chemokine receptor CXCR4 on CD34+ cell surface and the chemokine stromal cell–derived factor 1, also known as CXCL12, is also observed to coincide with serum proteases during G-CSF and chemotherapy, such as cyclophosphamide in human bone marrow.[291] With decreased chemotaxis signals within the marrow, the free-floating CD34+ hematopoietic stem cells can traffic toward the peripheral blood compartment.[292] With G-CSF, chemotherapy, and possibly plerixafor mobilization, peripheral blood circulating CD34+ hematopoietic stem cells can be increased to approximately tenfold to a hundredfold.

Many centers are also evaluating the use of UCB as a source of allogeneic hematopoietic stem cells. The use of UCB as an alternate source of allogeneic hematopoietic stem cells was first reported by Gluckman and colleagues in 1989.[293] Since that time, hundreds of UCB transplants have been performed in North America and Europe.[294] Because of the success of UCB transplantation in both related and unrelated donor settings, many cord blood banks (CBBs) have been established worldwide. UCB is collected from umbilical cord or placental veins after delivery of the infant and therefore is a readily available component. Parents have the option of banking the cells for their own use in a private CBB or donating them to a public CBB. If the UCB samples are donated to public CBBs, these cells undergo stringent quality-control evaluation; only qualified products are processed and cryopreserved for use. The UCB products stored in public CBBs are available for public use when requested and prescribed by appropriate transplantation physicians. The number of CBBs and the size of the inventory within the CBBs have been increasing.[295] There are at least 15 public CBBs in the United States. UCB transplantations offer many advantages: Various reports claim that UCBs are less immunogenic, and transplants may be performed across HLA barriers with less risk of GVHD than would be anticipated if a bone marrow donor with the same HLA type were used.[296] Therefore UCB transplant is an attractive alternative for patients requiring allogeneic transplantation who do not have an HLA-matched donor. In contrast to mobilized peripheral blood stem cells and bone marrow harvests, the collection of UCB after birth carries no risk for the donor. The collected UCB is HLA typed, tested for infectious agents, and banked for use—and therefore available immediately on request to be shipped to any transplant center in the world. Despite the ease of availability and safety of the donation procedure, UCB transplants have limitations. Studies continue to show that appropriate stem cell dose is essential for speedy hematopoietic cell engraftment and successful transplantation.[297-299] The limited cell dose in the UCB products poses problems especially for large adolescent and adult recipients. In the case of disease progression or relapse, it is also impossible to go back to the original UCB donor for lymphocyte or additional stem cell collections. Research working on the expansion of cord blood stem cells is ongoing.[300,301] Double UCB transplantation in adult patients is being attempted to overcome the dosing limitation issues.[302]

Infusion-Related Toxicities

Infusion of hematopoietic stem cell products can be associated with either immediate reactions or long-term side effects. The immediate infusion toxicities are similar to blood transfusion reactions. They include febrile reactions resulting from infusion of large number of leukocytes and related cytokines, allergic reactions secondary to plasma protein content, and occasional hemolytic reactions caused by donor-recipient erythrocyte ABO incompatibility. To reduce the occurrence of febrile and allergic reactions, patients are always premedicated with antipyretic medication and antihistamines before hematopoietic stem cell infusion. Special manipulation to reduce the erythrocyte contents can be performed to prevent hemolytic reactions. For hematopoietic stem cell products or lymphocytes that are cryopreserved in dimethyl sulfoxide (DMSO) for storage in liquid nitrogen, the infusion of thawed products can lead to frequent DMSO-related toxicities. Common symptoms attributed to DMSO include nausea, vomiting, flushing, and headaches. Anaphylactoid symptoms caused by the release of histamine are also common. Embolic events associated with infusion of bone marrow and apheresed hematopoietic stem cell products have been reported. Most of the described cases involved infusing of products with particulate matter, owing to cell clumps or bone fragments, in recipients with congenital cardiac septal defect.[303,304]

GVHD is the most common long-term toxicity associated with allogeneic HSCT. Approximately 30% to 70% of patients undergoing allogeneic HSCT will develop GVHD.[305] GVHD is mediated primarily through donor graft lymphocytes (T-cell population). Graft lymphocytes target tissues with alloantigens and cause alloimmune reactions in recipient organs.[306,307] Severe GVHD is observed when donors are not fully identical at MHC antigens (HLA-A, B, DR) with the recipient. However, most allogeneic HSCTs are conducted with donors and recipients who are identical at MHC antigens. In these recipients minor histocompatibility antigens (mHAs) are thought to be the primary targets of donor alloimmunity, and severe GVHD can occur.[308-310] Studies have shown that mHAs can be expressed on hematopoietic tumor cells. When donor T cells target leukemia mHAs, alloimmunity results in graft-versus-leukemia (GVL) and can contribute to eradication of leukemia cells.[311,312] The use of donor lymphocytes as adoptive immunotherapy for patients with relapse of chronic myelogenic leukemia has shown to be successful in patients in cytogenetic relapse after allogeneic HSCT.[313-315] Conversely, depletion of T-cell content in the graft has shown to reduce the incidence of GVHD but at the expense of losing GVL effect.[307]

Component Assessment

For customized cell therapy such as HSCT, each product is donor-patient specific. The quality of the product varies for different donors and even changes daily for a product that came from the same donor. As mentioned previously, the content of the product can lead to various types of infusion reactions, immunologic effects, and time to hematopoietic cell engraftment. Most important, as with any blood product, infusion of products with microbial or viral contamination can lead to transmission of infectious diseases.

Achieving rapid hematopoietic cell engraftment is essential for successful HSCT. Insufficient infusion of hematopoietic stem cells is linked to prolonged hematopoietic cell recovery. Patients who experienced delayed hematopoietic engraftment require long-term blood component support and are more likely to contract severe bacterial, fungal, and other opportunistic infectious disease as a result of prolonged neutropenia and lack of proper immune function. Functional assays such as granulocyte-macrophage colony-forming unit (CFU-GM), granulocyte-erythroid-macrophage-megakaryocyte colony-forming unit (CFU-GEMM), and long-term culture–initiating cell (LTC-IC) content have been described as measures of hematopoietic stem cell quality and content. The results of these assays correlate well with posttransplantation hematopoietic recovery. However, these culture-based assays have long turnaround times. Enumeration of CD34+ cells using flow cytometry analysis is now commonly performed as a surrogate for hematopoietic stem cell content because of its fast turn-around-time and proven correlation with clinical engraftment data. As with other assays, CD34+ cell enumeration methods vary among centers, making the characterization of a hematopoietic stem cell component that is adequate to achieve hematologic engraftment more difficult.[316,317] Standardized protocols for CD34+ cell enumeration have been proposed in an attempt to limit variability and permit comparison of hematopoietic stem cell content of components collected and infused at different centers.[318] Methodologies to determine absolute cell concentrations instead of percentages may further improve the accuracy of the CD34+ cell enumeration procedure.[319] Analysis of graft T-cell content using flow cytometry in hematopoietic stem cell or donor lymphocyte products is also used to correlate with GVHD outcome.

In addition to quantifying hematopoietic stem cell content, components must be tested for contaminants. Contamination rate increases with component manipulation, such as ex vivo cell isolation or depletion and long-term cell culture, and may be associated with adverse clinical sequelae. This emphasizes the need to include bacterial cultures as a component of quality control of hematopoietic cell collection, processing, cryopreservation, thawing, and re-infusion procedures.[320]

Lastly, critical evaluation of the donor of the product is also essential in assessing the quality of the product. All allogeneic and autologous products should be tested for infectious disease markers, just like those from routine blood donors. Donors who are positive for certain viral markers can still donate their cells for transplantation if the transplantation was deemed as the only life-saving option and the patient was informed of the risk by the transplant physicians. However, the practice of using high-risk allogeneic donors for transplantation is discouraged.

Processing and Storage of Hematopoietic Progenitor Cell Components

Autologous and, occasionally, allogeneic hematopoietic progenitor cell components are collected before the patient receives myeloablative therapy and are cryopreserved. Cells are suspended in a mixture of an electrolyte solution, a protein source and a cryoprotectant such as DMSO or hydroxyethyl starch.[321] Cryopreserved cells are infused rapidly when thawed, and the freezing solution can be infused along with the cells. Premedication is required to minimize toxicities.[322-324]

In the allogeneic setting, processing may be performed to prevent acute hemolysis associated with infusion of an ABO-incompatible component.[325] If there is a major ABO incompatibility, which occurs when the recipient's plasma contains antibodies against donor RBCs, many centers will remove RBCs from the donor component. If there is a minor ABO incompatibility, wherein the donor plasma contains antibodies against the recipient's RBCs, the component will be washed or volume reduced to remove plasma. Alternatives to these procedures include plasma or RBC exchange in the recipient as well as the infusion of sources of donor blood group antigens to absorb recipient antibodies.[326,327]

Laboratories may perform more extensive procedures in an attempt to deplete unwanted cell populations from the hematopoietic stem cell component. Tumor cells are removed from autologous components in an attempt to decrease the risk for relapse, whereas T lymphocytes are removed from allogeneic components to abrogate acute GVHD. Most of these procedures are performed using either negative- or positive-selection methods.

Negative selection targets the cells to be removed from the component while preserving other cell populations.[328] The methods for negative selection that have been used include attempting to separate cells on the basis of physical characteristics, in vitro sensitivity to chemotherapeutic agents, and monoclonal antibody (MoAb)–mediated separation or damage. Density gradient centrifugation and counterflow centrifugal elutriation have been used to separate cells according to size. Trials have used 4-hydroxycyclophosphamide or mafosfamide to kill tumor cells. Cells can bind to MoAbs conjugated to magnetic beads, dense particles, or surfaces and be physically separated from the other cell populations within a component. In addition, MoAbs may be used to destroy tumor cells or T cells by way of conjugation with toxins or complement-mediated lysis.[329]

In contrast, positive selection enriches the cell population to be retained while nonspecifically depleting all other cell populations. The systems currently available for positive selection use MoAbs directed against various hematopoietic cell surface antigens. Cells are incubated with the MoAbs, and separation is achieved by biotin-avidin, magnetic bead, or high-speed cell-sorting methods.[330-333] Most of these cell-manipulation techniques are initially designed to reduce the incidence of GVHD or disease relapse associated with HSCT. Recently, some of these techniques have also been applied to the development of cell-based immunotherapy. For example, monocytes or

CD34+ cells from peripheral blood can be isolated using selection techniques and treated in vitro so that the cells differentiate into potent antigen-presenting dendritic cells. Animal models have shown that dendritic cells can act as tumor vaccines to stimulate and enhance cell-mediated immunity in patients who may have defective tumor immunity.[334-336] Specialized lymphocytes can also be isolated and expanded with appropriate growth factors and antigen stimulation to target specific tumor cells or infectious agents. Most of the cell-based immunotherapies are still under investigation and therefore considered experimental. Encouragingly, early clinical data using dendritic cell therapy in melanoma-, prostate cancer–, and Epstein-Barr virus (EBV)–specific T cells targeting posttransplant lymphoproliferative diseases have shown immunologic responses with potential clinical effects.[337-340]

Future Directions

Several areas of active investigation involve the use of hematopoietic stem cells. First, definitive trials are necessary to clarify whether there is any clinical benefit associated with CD34 positive cell selection, tumor cell, or T-cell depletion. Second, building on platforms where cells have been expanded but differentiated,[341] as new cytokines are identified and new systems developed, it may be possible to expand primitive hematopoietic stem cells. Expanded populations of primitive cells would be useful for infusion to patients whose autologous graft contains insufficient numbers for transplantation. In addition, the ability to expand hematopoietic stem cells could make UCB components available to larger recipients with less perceived risk. In addition, expanded cells may be useful for gene therapy approaches.

Much effort has taken place in recent years to use hematopoietic stem cells as a strategy for clinical gene therapy or to use other cells therapeutically. Stable expression of a transgene in a primitive hematopoietic stem cell would, in theory, be an ideal method to replace missing gene products in a patient. However, some retroviral vectors induce leukemia owing to insertional mutagenesis of CD34+ cells.[342] Current studies are using vectors designed to minimize the risk of oncogenesis and are aimed at treating severe congenital diseases involving the hematopoietic system.[343]

APHERESIS

Apheresis (from the Greek *aphairesis*, meaning "removal") refers to a technique of drawing peripheral blood, separating it, and selectively removing one or more of the components while returning the remainder. Apheresis techniques may be manual or automated, and the phases of drawing, separating, removing, and returning blood and components may be continuous or discontinuous. The technique of apheresis may be used for collecting transfusable blood components from donors, and it may be used to treat patients with conditions for which removal or replacement of a portion of the blood may be therapeutic. The terms *cytapheresis, erythrocytapheresis, leukapheresis, plateletpheresis,* and *plasmapheresis* refer to the use of apheresis to remove, respectively, cells, RBCs, white cells, platelets, or plasma. The terms *plasma exchange* and *RBC exchange* imply that the component removed is replaced in like amount with normal plasma or RBCs. In practice, nearly all donor and therapeutic apheresis is performed using automated techniques with specialized programmable separation devices designed for this purpose.

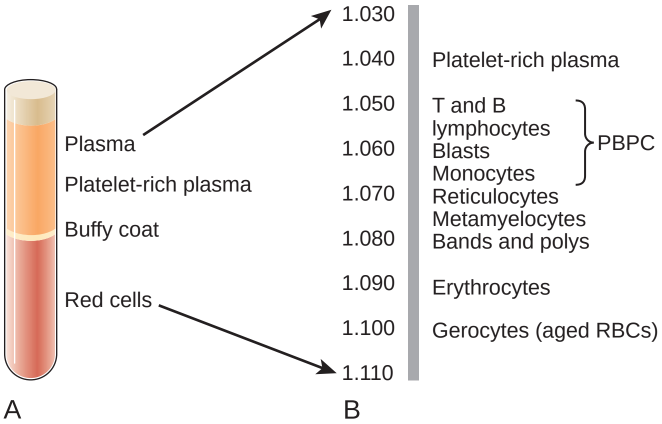

Figure 36-6. **A**, Separation of anticoagulated whole blood. **B**, Specific gravity of blood components. *PBPC,* Peripheral blood progenitor cells; *Polys,* polymorphonuclear leukocytes; *RBCs,* red blood cells.

The principle by which most apheresis instruments fractionate the components of whole blood is simple density centrifugation. The instrument contains a sterile, closed, and disposable centrifugation chamber in which whole blood is separated into RBC, plasma, and buffy-coat layers. The densest component, the RBCs, is segregated to the bottom of the centrifugal field, the least dense component (plasma) is pushed to the top, and the other cellular components layer in between, as shown in Figure 36-6. The efficiency of separation depends not only on the density of the components but also on the geometry and rotational speed of the centrifugal chamber and on the specific technique for isolating the separated layers. Pure separation of plasma from RBCs and concentrated suspensions of platelets nearly devoid of RBCs can be achieved reliably. Because the white cell layer is much smaller than either the RBC or plasma layers and close in density to the RBC layer, both the RBC and the platelet components will contain leukocytes. For the same reason, whereas it is possible to use apheresis to isolate leukocyte fractions that are enriched in granulocytes, or in mononuclear cells, these fractions will also contain other types of white cells as well as RBCs and platelets.

Other apheresis instruments separate blood by filtration rather than centrifugation. Because this technique cannot separate cellular elements, it is used primarily in donor applications for collection of plasma.

Donor Apheresis

Overall, the most common medical use of automated apheresis technology is for donor procedures, in which platelet or plasma is collected from individual volunteer donors. The principle reason to use apheresis techniques to collect these products, rather than deriving them from whole blood donations, is that the yield per donation is much higher. Six to 20 times the number of platelets can be harvested in one apheresis donation than can be isolated from one unit of whole blood. Automated systems can be programmed to collect two or even three separate blood components from one donor during a single apheresis procedure—that is, units of packed cells, plasma, or single-donor platelets. The same advantage applies to these apheresis collection techniques. A much larger yield is obtained per donation, with little or no compromise in donor safety. The blood products derived from these donor procedures have slightly different quality-control characteristics from WBD components, but in clinical use they are as efficacious as those derived from whole-blood donations.

Granulocyte concentrates drawn by apheresis technology to treat refractory fungal or bacterial infections in patients with profound neutropenia are once again being evaluated.[344] Studies in the 1970s showed that granulocyte transfusions had limited efficacy and considerable toxicity. However, the advent of a granulocyte-specific hematopoietic cytokine (G-CSF) in concert with apheresis technology has made it possible to collect up to tenfold more granulocytes for transfusion than were available for the older studies.[345] Unlike products from unstimulated donors, granulocyte concentrates collected with cytokine stimulation of the donor can yield substantial increments in peripheral granulocyte count in the recipient.[346,347] Whether these larger increments correspond to greater efficacy and tolerable toxicity has yet to be determined.[348-351]

Apheresis technology can also facilitate obtaining multiple units of plasma from the same donor to provide single-donor plasma support to a recipient with a congenital coagulation factor deficiency treatable with plasma, such as factor X or XIII deficiency.

Although adult-donor apheresis, especially for platelet collection, has a large impact on the blood banks that supply blood products for pediatric patients, child-donor apheresis is rarely used. The one exception is donor apheresis collections of peripheral blood progenitor cells, described later.

Therapeutic Apheresis

A broad spectrum of indications exists for automated apheresis used for therapeutic effects in children. For some indications the mechanism of the therapeutic benefit is readily apparent and the efficacy of the treatment well substantiated. For many other indications the rationale for use of apheresis to treat a disease condition is less clear and is based on extrapolation from studies in adults or on anecdotal evidence. It is important to remember that the therapeutic value may be derived from the removal of a portion of the patient's blood, from the administration of a fluid to replace what was removed, or from both. In some cases the therapeutic value of an apheresis procedure is derived from the ability to control the patient's blood volume independent of the rate and total volume of blood product administered, as with complete exchanges of the RBC mass or the plasma volume.

Manual Apheresis

Although it is theoretically possible to carry out most apheresis procedures by entirely manual techniques, with steps analogous to those used to make blood components from donated whole blood, in practice, manual methods are usually reserved for situations in which the automatic equipment is not available or in which the volume of blood to be processed is too small to warrant use of the automated cell separator. For example, for a newborn with isoimmune thrombocytopenia, it might be possible to obtain an adequate dose of platelets by drawing one unit of whole blood from the mother, isolating the platelets manually, and transfusing the residual RBCs and plasma back to the mother, rather than subjecting the mother to an automated plateletpheresis procedure. Another manual apheresis procedure is the whole blood exchange for neonatal hyperbilirubinemia, typically performed in a discontinuous fashion with reconstituted whole blood, an empty blood-collection bag, a three-way stopcock, and a syringe to remove and replace blood in 10-mL cycles. Occasionally a manual exchange of RBCs or plasma may be the only alternative in a patient whose venous access is inadequate for an automated exchange and for whom a simple transfusion is not an alternative.

Automated Apheresis

Modern apheresis machines offer the advantages of a sterile, closed, single-use system; automated control of volume balance; traps to prevent air embolism; and other safety features. Each machine can perform several types of apheresis procedures, with highly automatic modes as well as the capacity to modify procedure parameters for individual patient needs. By comparison, manual exchanges are more awkward to perform, usually use open systems, involve manual tracking of intake and output, and are therefore potentially less safe. Apheresis devices may be either continuous or discontinuous. A discontinuous device withdraws a volume of blood, separates it, removes the selected component, and returns the remainder, all in serial steps. The sole advantage of a discontinuous device is that it requires only a single site of vascular access. In the donor setting this is often reason enough to use a discontinuous device. However, compared with a continuous device, discontinuous apheresis technique requires longer processing times and involves larger volume shifts in the donor or patient. The latter consideration may be critically important in pediatric patients and imposes a practical limitation on the use of these devices in children. In contrast, continuous devices withdraw, separate, and return blood simultaneously, permitting apheresis procedures that affect the patient's intravascular volume only minimally.

For any apheresis procedure, there is a fixed extracorporeal blood volume and extracorporeal RBC mass that must be taken into account in planning the procedure. The extracorporeal blood volume depends on the specific make and model as well as the type of procedure planned and fall into a range from 100 to 400 mL.

Unique Aspects of Apheresis in Pediatrics

Performing apheresis procedures in pediatric patients is often more challenging than performing analogous procedures in adults. The specific challenges include vascular access, anticoagulation, volume shifts, hypothermia, and patient cooperation.

Vascular Access

The vessel used for the apheresis draw line, through which whole blood is drawn into the extracorporeal system, must be large and resilient enough to accommodate a large catheter and to sustain the required flow rate without collapsing. When peripheral veins are used, a rigid needle, 18 gauge or larger, is used for drawing. In adults and older children, it is usually possible to find veins in the antecubital fossae large enough to accommodate this needle, but children under the age of 7 years often do not have adequate access. The access requirements for returning blood are less demanding because a smaller gauge (20 to 22 g) flexible catheter may be used. Although every child undergoing apheresis should be evaluated first for peripheral access, it is often necessary to obtain access to a larger central vessel. This may be accomplished in several ways: a single-lumen central vein catheter or an arterial line to draw, and a peripheral vein to return, or a double-lumen venous catheter. The catheters, often referred to as “dialysis catheters” because the same access issues apply in hemodialysis, may be designed either for temporary placement (usually stiff, straight catheters intended for bedside percutaneous placement) or permanent (softer, tunneled catheters with cuffs that require placement in the operating room).[352] Temporary polyurethane catheters are available as small as 7 French for patients as small as 5 to 10 kg. Permanent catheters designed for apheresis are available as small as 8 French, for children as small as 10 to 12 kg.[353] It is important to realize that most of the double- and triple-lumen catheters available for general purpose central access in children may fail under the draw pressure of an apheresis procedure because the lumen is too small or the catheter wall too soft. Some multiple-lumen catheters also have inadequate separation of the openings of the lumens, permitting recirculation and decreasing the efficiency of apheresis.[353] Hence it is imperative to consider the possibility that apheresis will be required before placement of a central catheter. Finally, there is growing experience with successful use of implanted access devices (ports) to support chronic apheresis therapy in children.[354,355]

Anticoagulation

Because the blood is exposed to artificial surfaces, apheresis procedures usually require an anticoagulant to prevent activation of platelets and the coagulation cascade and the formation of clot within the extracorporeal circuit. The standard anticoagulants used in apheresis are sodium citrate, heparin, or combinations of those two. The anticoagulant is added to the circuit at a controlled rate just at the point where the blood is drawn, and a portion of the anticoagulant is eventually returned to the patient. The amount of anticoagulant that the patient receives depends on the type of procedure, the replacement fluid, and the rates of blood drawing and replacement.

Citrate chelates the available calcium, a necessary cofactor for the clotting cascade, and also prevents platelet aggregation. The infusion of citrated plasma or blood does not cause systemic anticoagulation in the donor or patient, but it may reduce the ionized calcium level in the plasma. Pediatric patients are particularly subject to citrate toxicity, in part because the flow rates used during apheresis procedures, and therefore the citrate doses, are often higher on a per-kilogram basis than for adults. Citrate toxicity first manifests as tingling around the mouth and fingers and sometimes nausea and abdominal discomfort. More serious citrate toxicity includes hypotension and cardiac rhythm disturbances.[356] Because a young or critically ill child may be unable to inform the operator about the earlier warning signs of citrate toxicity, use of citrate as an anticoagulant requires careful attention to ionized calcium levels, calcium replacement by mouth or by intravenous infusion,[91] and monitoring of blood pressure and heart rate.

Alternatively, citrate may either be replaced or supplemented with heparin anticoagulation, which may be monitored by activated clotting time, a crude measure of whole-blood clotting time.[357,358] Heparin anticoagulation may be achieved with a bolus, with or without subsequent continuous infusion. The dose of heparin used for an apheresis procedure is similar to doses used for therapeutic anticoagulation, and the patient may be expected to have a systemic anticoagulation effect lasting 4 to 6 hours after the end of the procedure, a side effect that may be significant in a patient who has had recent surgery or is otherwise at risk for bleeding. Citrate confers minimal bleeding risks, and citrate without heparin is generally used to anticoagulate patients with bleeding risks.

Volume Considerations

The extracorporeal volume for an apheresis procedure, including the centrifugal chamber, tubing, filters, air traps, and possibly a blood warmer, may exceed 400 mL, depending on the machine and tubing configuration. Because the majority of this extracorporeal volume will consist of whole blood or packed cells within the centrifugal chamber, there is also an obligate extracorporeal RBC mass. Discontinuous machines carry out stepwise cycles of removal and return of the extracorporeal volume. In a continuous apheresis machine, the extracorporeal volume is filled at the start by drawing blood from the patient and remains fixed through the duration of the procedure. An older child or an adult with a blood volume of approximately 5000 mL can usually tolerate the temporary loss of 300 to 400 mL of blood in either a discontinuous or a continuous technique. At the other extreme, for a child of 12 kg with a blood volume of about 800 mL, the extracorporeal volume represents roughly half the patient’s blood. Thus for younger children discontinuous apheresis technique is not feasible, and continuous apheresis procedures may require priming with exogenous RBCs, reconstituted whole blood, or albumin to compensate for the extracorporeal volume and RBC mass.

Many apheresis devices have automated modes that at completion of the procedure return the RBCs in the circuit to the patient by flushing with saline. This return cycle results in rapid reinfusion of up to 450 mL over several minutes. An older child or adult, who was able to tolerate the temporary loss of volume and RBC mass incurred during a discontinuous or unprimed continuous apheresis procedure, will usually tolerate the rapid return of the volume. However, a younger patient may not tolerate the return cycle, which means that some or all of the obligate extracorporeal RBC mass must be left in the machine. This loss of RBC mass must be compensated for by using packed RBCs as the priming fluid at the start of the procedure.

Beyond the principles that have been described here, there are also strategies to avoid fluid overload without the use of RBC priming, to administer or remove intravascular fluid, and to administer blood products during the course of an apheresis procedure. The apheresis physician must take into consideration the patient's size, the extracorporeal volume of the apparatus in use, the patient's RBC mass and volume status, and disease factors that may affect the patient's ability to tolerate rapid changes in blood volume and RBC mass. The management of volume and RBC balance during apheresis procedures in children requires careful, individualized planning and a thorough understanding of the operation and programming of the automated cell separator.

Hypothermia

Because a portion of the patient's blood volume circulates outside the body during apheresis, considerable heat loss to the environment can occur. Adult platelet donors may lose sufficient heat to require blankets by the end of a 90-minute collection. For children undergoing apheresis, the physiologic impact of this heat loss is much greater, and the use of a blood warmer may be required to prevent life-threatening hypothermia. The amount of heat loss is a function of: (1) the ratio of extracorporeal volume to patient's blood volume, (2) the rate of blood removal or replacement, and (3) the thermal properties of the system. A blood warmer reduces this heat loss at the expense of increasing the extracorporeal volume, albeit modestly. Only approved devices should be used to warm the blood.

Other hazards of therapeutic apheresis are rare. These include some severe complications, but they appear to be largely related to the underlying disorder as opposed to the apheresis itself.[358,359] This is consistent with the rarity of serious complications in apheresis platelet donors. Complications have also been reported in pediatric series. However, more were related to the need for vascular access than to the procedure itself.[357,360]

Cooperation

The staff of a pediatric apheresis unit must be proficient in age-appropriate communication and psychosocial support. The aspects of the apheresis procedure that are most upsetting to children are the needle sticks, the need to remain seated, the immobilization of one or both arms, the frequent squeezing of the blood-pressure cuff, and boredom with a prolonged procedure. Expertise in phlebotomy and placement of intravenous lines is a basic requirement for the staff. The other issues can usually be managed with age-appropriate explanations, parental involvement, and distracting entertainment. Sedation is almost never necessary, although extremely uncooperative patients, such as those with a significant psychiatric diagnosis or movement disorder, might require sedation unless central access is used.

Indications

A consensus committee for the American Society for Apheresis has periodically reviewed the apheresis literature supporting and refuting the use of apheresis-based therapies for a variety of disorders in which it has been tried (Table 36-11).[361] For each disorder the strength of the evidence supporting the efficacy of apheresis was evaluated and the indication placed into one of five categories. Category I means that efficacy is well documented and use of therapeutic apheresis is "standard and acceptable"; category II, that apheresis is probably efficacious and its use is "generally accepted" but as an adjunct to primary therapy; category III, that efficacy is debatable and evidence is mostly anecdotal or conflicting; category IV, that apheresis has been shown to be ineffective and use of apheresis should be "discouraged"; and category P (for Pending), wherein an apheresis device is not approved for use in the United States, although trials may be under way. Table 36-11 is excerpted from the consensus review, listing only those diagnoses usually encountered in the practice of pediatric apheresis.[362]

ERYTHROCYTAPHERESIS (RED BLOOD CELL EXCHANGE) FOR SICKLE CELL DISEASE

In sickle cell disease small-vessel occlusion occurs when RBCs deformed (sickled) by polymerized Hb S obstruct blood flow in capillaries. If the percentage of cells that can be deformed in this way is reduced below 30% to 50% by transfusion with normal RBCs, many of the clinical manifestations of sickling substantially decrease. This reduction can be accomplished either by serial simple transfusion or by erythrocytapheresis. When a rapid reduction in the percentage of Hb S–containing cells is desirable, such as in the acute management of stroke or chest syndrome or preparation for emergency surgery, erythrocytapheresis is the method of choice. A series of two to four simple transfusions given over 2 to 3 weeks can also reduce the percentage of Hb S–containing cells to less than 30%, an approach suitable for preparation for elective surgery.

Acute Chest Syndrome

Acute chest syndrome is a leading cause of premature death among patients with sickle cell disease. Transfusion with RBCs is commonly used to treat acute chest syndrome, both to increase the oxygen-carrying capacity of the blood and to reduce the percentage of Hb S. Although controversy exists regarding the advantages

Lung transplant	Extracorporeal photopheresis	III

From Shaz BH, Linenberger ML, Bandarenko N, et al: Category IV indications for therapeutic apheresis: ASFA fourth special issue. J Clin Apher *22:176-180, 2007.*

ANCA, Antineutrophil cytoplasmic antibody; *GBM,* glomerular basement membrane; *GBS,* Guillain-Barré syndrome; *GVHD,* graft-versus-host disease; *HUS,* hemolytic-uremic syndrome; *NS,* not specified; *P,* pending; *PANDAS,* pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections; *RPGN,* rapidly progressive glomerulonephritis; *TTP,* thrombotic thrombocytopenic purpura.

*I: Therapeutic apheresis is standard and acceptable, either as primary therapy or as a valuable first-line adjunct to other initial therapies. Efficacy is documented by controlled clinical trials and published experience.

II: Therapeutic apheresis is generally accepted as supportive to other more definitive treatments; there is some literature support of its efficacy.

III: Anecdotal reports may suggest the use of therapeutic apheresis; however, no controlled trials have documented its efficacy. No consensus can be reached regarding its risk-to-benefit ratio.

IV: Controlled trials show lack of efficacy of therapeutic apheresis. Anecdotal studies suggesting efficacy have not been reproduced.

of exchange transfusion over simple transfusion (see Chapter 20), the efficacy of both methods in acute chest syndrome is probably similar.[363] In practice, exchange transfusion by automated apheresis is often performed in severe acute chest syndrome to reduce the Hb S percentage in a shorter time, and without the accompanying fluid loading and increases in hematocrit concentration, than could be achieved by simple transfusion or manual exchange.[141]

Stroke

The observed incidence of stroke in patients with sickle cell disease varies from 6% to 34%. Although transfusion therapy is not thought to affect the neurologic outcome of completed strokes, it remains the mainstay of acute management as a measure to halt progression of cerebral vasculopathy. Considerable evidence suggests that long-term transfusion after a central nervous system event is effective prophylaxis against progression of central nervous system disease and against recurrence of clinical stroke (secondary stroke prevention).[364] Transfusion has also been shown to be effective in primary prevention of stroke in patients with sickle cell disease who have been identified as high risk on the basis of transcranial Doppler ultrasound studies of blood flow velocity in the circle of Willis.[365] For secondary stroke prevention, some neurologically stable patients may be maintained safely at a target Hb S concentration of less than 50%, which is usually easily achievable on a program of chronic erythrocytapheresis.[366] For primary stroke prevention, the standard approach is to maintain the hemoglobin S percentage at less than 30%, which is also achievable for most patients using erythrocytapheresis.

Priapism

Although prepubescent priapism has a good prognosis for eventual potency, multiple episodes of postpubescent priapism are associated with eventual impotence. In addition, there is some correlation of the duration of the episode of priapism with loss of erectile function. Whether this is because of efficacious therapeutic intervention or simply because the worst cases last longer and are more likely to cause irreversible damage remains unclear. Some authors advocate RBC exchange for severe cases,[367] but the efficacy of exchange transfusion for priapism in sickle cell disease is unclear.

Red Blood Cell Exchange for Chronic Transfusion

Erythrocytapheresis has an important role to play in chronic transfusion therapy in sickle cell disease. Children with sickle cell disease who develop complications for which chronic, lifelong RBC transfusion is indicated are at risk to develop transfusional iron overload. Although this can often be successfully managed with chelation therapy, patient responses are variable and chelation therapy does not always succeed in achieving and maintaining optimal iron concentrations. The iron overloading of long-term simple transfusion therapy can be substantially reduced or eliminated by a program of erythrocytapheresis.[368] This approach involves removal and replacement of approximately half of the patient's RBC mass every 3 to 4 weeks. Transfusion by erythrocytapheresis will generally require 23% to 73% more donor units and exposures than simple transfusion. Because the general risks of infectious disease transmission and transfusion reactions are low, the additional risk of these donor exposures may be outweighed by the benefit of reducing or avoiding iron overload and chelation therapy. Of greater concern is the relatively high risk for RBC alloantibody formation in patients with sickle cell disease. It is not clear whether patients chronically transfused by erythrocytapheresis have a greater risk of alloimmunization than those treated by simple transfusion because both populations will eventually receive large numbers of donor exposures.

Normovolemic Red Blood Cell Transfusion

RBC transfusion in hemodynamically unstable patients may be accomplished in a normovolemic fashion using apheresis technology. For example, thalassemia patients with end-stage cardiac failure secondary to transfusional iron overload may better tolerate transfusion to raise the Hb if the blood volume is not increased rapidly. Exchange transfusion in the setting of overwhelming hemolysis has also been advocated when transfusion requirements would exceed the patient's ability to handle the volume to be transfused. This may occur in autoimmune hemolytic processes (especially IgM-mediated ones) as well as in infectious hemolytic processes, including malaria and babesiosis.[369,370]

Erythrocytapheresis may also be used to remove RBCs from a patient or donor. Patients with polycythemia secondary to chronic cyanotic congenital heart disease, complicated by Eisenmenger's syndrome, may have improved hemodynamic function and symptomatic relief after phlebotomy, which is well tolerated using apheresis technology.[371] Finally, more than one unit of RBCs at a time can be drawn safely from a donor if normovolemia is maintained.[372] This technique is being used increasingly in routine red cell collection,[373,374] in autologous red cell collection,[175] and is especially useful when obtaining blood from rare donors or from a single donor to support a specific recipient.

LEUKAPHERESIS

Leukocytosis is a negative prognostic indicator in childhood leukemia, especially when the presenting white blood cell count exceeds 200,000/μL. In many centers it is standard practice to perform leukapheresis or whole blood exchange for patients presenting with extremely high counts, with the goal of treating or preventing symptoms related to hyperviscosity and tumor lysis syndrome.[375] Although the leukocyte count can be reduced rapidly, typically dropping by 50% to 75% immediately after the procedure, a long-term survival advantage for patients treated by leukapheresis for hyperleukocytosis has not been demonstrated. The value of this intervention may in part depend on the presenting immunophenotype. Specifically, complications of hyperleukocytosis, such as cerebral thrombosis and hemorrhage, are more common in acute myeloblastic leukemia than in acute lymphoblastic leukemia.[376] Furthermore, in one retrospective study electrolyte abnormalities during induction chemotherapy were reduced in the group of patients with acute lymphoblastic leukemia presenting with hyperleukocytosis who received leukapheresis or exchange transfusion, suggesting that leukapheresis may reduce the severity of tumor lysis syndrome.[377] Some authors propose that all patients with acute myeloblastic leukemia or acute undifferentiated leukemia with presenting white blood cell counts in excess of 200,000/mm^3 should undergo exchange or leukapheresis, whereas only selective patients with acute lymphoblastic leukemia require this intervention.[378] Technically, leukapheresis may be performed either by using specific tubing sets designed to remove the buffy-coat layer or by using the tubing set for plasmapheresis and collecting down into the RBC interface. It is often desirable to maintain a relatively low hematocrit concentration during therapeutic leukapheresis because the RBC mass contributes to the viscosity of the blood.

PERIPHERAL BLOOD PROGENITOR CELLS

Peripheral blood progenitor cells or stem cells are hematopoietic progenitors with the potential for self-renewal that circulate in the blood. At steady state they are present in very low numbers, but during the early phase of recovery from chemotherapy-induced myelosuppression or as a result of exogenous hematopoietic cytokine mobilization (e.g., G-CSF), their relative numbers may increase tenfold to a hundredfold. This observation has made it possible to collect sufficient numbers of progenitor cells by apheresis to allow autologous hematopoietic rescue after high-dose chemotherapy and to serve as the sole source of stem cells, in lieu of bone marrow, for allogeneic transplantation.[379-382] Collection of peripheral progenitor cells for autologous transplantation in children was reported in 1989 by several centers.[379-382] Early engraftment of granulocyte and platelets after high-dose chemotherapy was observed, similar to the findings in adult trials.[383] (See Chapter 8 for a discussion of the role of HSCT and evaluation of progenitor harvests.)

Because almost all pediatric autologous peripheral blood progenitor protocols are directed toward treatment of aggressive cancers with high risks of relapse (e.g., relapsed lymphoma, high-risk brain tumors), the protocols have most commonly timed the collection of cells to occur during the initial rise in white blood cell count after chemotherapy-induced myelosuppression. Most protocols also use mobilization with a hematopoietic cytokine (G-CSF).[384-388] The general considerations for access for progenitor cell collections are the same as have been described previously. Because many of the candidates for peripheral blood progenitor cell collections will have central lines for their chemotherapy and supportive care placed at the time of diagnosis or relapse, it is important to select a catheter stiff enough to use in leukapheresis. As with large-volume leukapheresis collections in adults, four to seven blood volumes may be processed by the cell separator in a single 4-hour apheresis collection. More prolonged collections are technically feasible and do increase the net yield but may tax the patience of the child and apheresis staff. The adequacy and quality of collections are usually monitored with a complete blood cell count and a measure of progenitor content, using either tissue culture assays for CFU-GM or, more commonly, counts of CD34+ cells by fluorescence-activated cell-sorter analysis, or both. Whereas a typical yield from a single collection in adults might be 2.5×10^6 CD34+ cells per kg of recipient body weight, yields from pediatric collections are often much higher. Actual yields vary widely, depending on factors such as history of previous chemotherapy, timing of collections, intercurrent illness, and precollection counts.[385-388] Cytopenias, especially thrombocytopenia, have been reported after progenitor cell collections,[389] but catheter-related problems such as mechanical obstruction, thrombosis, and infection are the most common difficulties.[390]

EXTRACORPOREAL PHOTOPHERESIS

Extracorporeal photopheresis is a therapeutic use of apheresis technology that takes advantage of the conversion by ultraviolet A light (UVA, spectrum 320 to 400 nm) of 8-methoxypsoralen from an inactive molecule to an agent that can induce irreversible lesions in the DNA of leukocytes. This induces apoptosis of re-infused leukocytes, which in turn can induce regulatory T cells and stimulate interleukin-10 production.[391,392] Disorders mediated by excessive autoreactivity or alloreactivity might theoretically be treated by this approach. Some photopheresis protocols involve performing leukapheresis to collect mononuclear cells, ex vivo psoralen treatment and UV irradiation of the cells, and re-infusion of the treated cells. In other protocols the patient is treated with the psoralen systemically before leukapheresis and UV irradiation of the product. The best-documented therapeutic effect of photopheresis is in the treatment of cutaneous T-cell lymphomas (Sézary syndrome found exclusively in adults), in which response rates greater than 60% and cure rates of 10% to 15% have been achieved.[393]

More recently it has been applied to treat rejection of solid organ grafts in which immunosuppressive interventions have failed and to treat chronic GVHD, especially skin GVHD, after bone marrow transplantation, including in children.[394-399] According to some anecdotal reports, striking responses have been observed in patients with cardiac rejection refractory to standard treatment, and a randomized pilot study demonstrated efficacy of photopheresis in prevention of cardiac allograft rejection.[400] Controlled trials are needed before the efficacy of this application can be evaluated.[401] Additional reports have been made describing the control of rejection of other solid organ transplants (including lung) by extracorporeal photopheresis.[402,403]

PLASMA EXCHANGE

Plasma exchange is performed either to remove harmful constituents of the plasma (e.g., autoantibodies, excess cholesterol) or to replace missing plasma proteins, such as coagulation factors in liver failure. The extent of removal of a particular molecule or compound by plasmapheresis is a function of the amount of plasma removed and of the distribution of the molecule in the body. The most efficient clearance is achieved for substances (e.g., IgM) that are limited to the intravascular compartment. If the molecule is distributed within the compartment defined by the extracellular water (e.g., IgG), then the efficiency of removal is also affected by the rate of reequilibration between the extravascular and the intravascular space. Plasmapheresis is least efficient when the molecule targeted for removal is distributed over the entire body (as with many drugs and toxins). Similarly, the efficiency of replacement of missing plasma factors is a function of the factors' distribution and ongoing rate of consumption.[357]

For some indications the underlying mechanism of an observed therapeutic effect of plasmapheresis may be unknown. For example, in TTP, controlled clinical trials[393] documented the superiority of plasma exchange over simple plasma transfusion well before the pathogenesis of the disease was understood. This result was commonly extrapolated to the treatment of HUS because it shares certain clinical features with TTP, even though the empiric evidence supporting the use of plasma exchange in adult HUS[404] and pediatric HUS[357,405,406] was not well founded. In light of the demonstration in patients with TTP (but not HUS) of an autoantibody that removes the activity of a serum metalloproteinase responsible for cleaving von Willebrand factor,[407-409] it appears that plasma exchange treats TTP by removal of the autoantibody as well as by replacement of the serum metalloproteinase and normal von Willebrand factor. Although this discovery has provided a sound explanation of how plasma exchange helps in TTP, it has invalidated the prior assumption that HUS and TTP represent a spectrum of a single disease process that will respond to plasma exchange.

The role of plasma exchange in liver failure is controversial. In acute severe liver failure, metabolic toxins (the so-called middle molecules such as ammonia that are not effectively removed by conventional dialysis) accumulate and lead to hepatic encephalopathy, coma, and death. Furthermore, failure of production of intravascular proteins, including albumin and coagulation factors, leads to ascites, edema, and bleeding. Plasma exchange can offer temporizing supportive care by providing the missing plasma components in larger doses than could be delivered by simple transfusion. However, plasmapheresis is inefficient for removal of the toxins that accumulate in liver failure and has not been shown to prevent or forestall the development of hepatic encephalopathy. The use of plasma exchange to provide a bridge to support patients awaiting liver transplantation or to normalize coagulation parameters immediately before transplant surgery is well documented.[410]

Autoimmune Disorders

Guillain-Barré Syndrome

Several controlled studies comparing plasmapheresis to conventional therapy for Guillain-Barré syndrome (GBS) have documented a therapeutic benefit from plasmapheresis, especially when initiated early in the course of the illness.[411] Lack of uniform response to plasmapheresis had led some researchers to speculate whether the syndrome may be a common outcome of diverse causes.[412] Because children with GBS have a somewhat better prognosis than adults, plasmapheresis is generally reserved for those who deteriorate rapidly or who require ventilator assistance.[413] High-dose intravenous immunoglobulin (IVIG) has also been shown to have efficacy in treatment of GBS, and a randomized trial in adults demonstrated that IVIG may be slightly superior to plasma exchange in GBS.[414] This result has led neurologists to treat with IVIG first and reserve plasmapheresis for refractory or especially severe cases. Both IVIG and plasmapheresis have efficacy in childhood GBS but have not been compared in a randomized trial[415,416] Patients with chronic inflammatory demyelinating polyradiculopathy, an insidious peripheral neuropathy with a waxing and waning course and some similarities to GBS, may also benefit from plasmapheresis.[416-418]

Myasthenia Gravis

Myasthenia gravis is a neuromuscular disorder characterized by progressive proximal muscle weakness. It follows damage to motor end plates owing to an autoantibody directed against postsynaptic acetylcholine receptors. Plasmapheresis has been shown to provide acute temporary relief of myasthenic crises and to be a useful adjunct along with immunosuppressive therapies for longer-term treatment.[419,420]

Systemic Lupus Erythematosus

Systemic lupus erythematosus is an autoimmune disorder with protean manifestations that may affect many organ systems, especially the skin, kidney, central nervous system, and blood. Controlled trials of plasmapheresis in systemic lupus erythematosus have generally failed to show long-term benefit.[421] Nonetheless, some authors advocate the use of plasmapheresis to treat certain acute flares of the disease, especially when they are severe or threaten the function of vital organs (e.g., kidney, central nervous system). Another proposed appropriate indication for apheresis is a lupus flare during pregnancy when other more toxic treatments might be contraindicated.[422]

Immune Hemolysis

Cold agglutinin disease, a form of autoimmune hemolytic anemia mediated by an RBC antibody of the IgM isotype, may be effectively treated in the acute phase by plasmapheresis, because IgM antibodies are efficiently removed by plasmapheresis.[423] Plasmapheresis has also been used in life-threatening IgG-mediated autoimmune hemolysis, even though the removal of IgG is much less efficient. The reduction in hemolysis is transient in either case, and in general, apheresis is warranted only to buy time until other treatments take effect or to treat disease refractory to other therapies.[424]

Other Autoimmune Disorders

Rasmussen encephalitis, a rare disease resulting in an intractable seizure disorder previously treated by hemispherectomy, has been shown to result from autoantibodies directed against the glutamate receptor (GluR3) in the brain.[425] The antibodies reportedly act as constitutive agonists, resulting in excessive neuronal activation and subsequent seizures.[426,427] Case reports suggest that plasmapheresis has a role in acute treatment. A syndrome called pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS) consists of a movement disorder with involuntary tics and a behavioral disorder with obsessive-compulsive features.[428] The pathophysiology is thought to involve group A β-hemolytic streptococcus triggering antibodies that cross-react with the basal ganglia of genetically susceptible individuals, a mechanism parallel to the pathophysiology of Sydenham chorea.[429] One randomized trial has demonstrated that both IVIG and plasma exchange have efficacy in treating the symptoms of PANDAS,[430] and another trial suggests that plasmapheresis and IVIG may have efficacy in Sydenham chorea.[431]

Hyper-IgE syndrome (Job syndrome) is a rare autosomal recessive disorder characterized by extremely high IgE levels, recurrent infections (typically with *Staphylococcus* organisms), and chronic dermatitis. Plasmapheresis results in a reduction of IgE levels and correspondingly decreases inflammatory lesions. It is usually reserved for patients who have failed to respond to other therapies, including antibiotics and IVIG.[432] An unusual complication of hyper-IgE syndrome is keratoconjunctivitis, which may threaten vision; it has reportedly been improved using apheresis.[433]

Other Coagulopathies

A preexisting coagulopathy has historically been a contraindication to putting a patient on ECMO, owing to the additional anticoagulation required to prevent clotting in the membrane oxygenation circuit and the high risk of intracranial hemorrhage. Several centers have observed that it is possible to perform plasmapheresis using the ECMO circuit itself, thereby replacing the missing coagulation factors with the hope of decreasing the risk of hemorrhage.[434,435]

Renal Disease

Cryoglobulinemia, a disorder rare in pediatrics, involves the pathologic production of proteins that reversibly precipitate or gel on exposure to cold. In general, they are antibodies, although they are not necessarily limited to the IgM class. These immune complexes may deposit in the kidney, resulting in end organ damage. Because they are largely intravascular, they are efficiently cleared by apheresis.[436] Apheresis has also been advocated in Goodpasture syndrome, an autoimmune disorder caused by antibodies against glomerular basement membranes. Controlled trials to measure the efficacy of plasmapheresis, often as an adjunct to other immunosuppressive agents, have yielded conflicting results. Some appear to show clear benefit,[437] whereas benefit in other studies appears marginal.[438]

Whereas plasmapheresis has not been shown to prevent renal allograft rejection, it may prove useful as an adjunctive therapy in preventing recurrence of corticosteroid-resistant nephrotic syndrome with focal sclerosing glomerulosclerosis (FSGS) in the transplanted kidney when used in conjunction with cyclophosphamide and pulse corticosteroids.[439,440] The mechanism of this therapeutic effect is thought to be the removal of a protein permeability factor in the plasma that mediates the renal injury in FSGS.

Hypercholesterolemia

Genetic absence of the low-density lipoprotein receptor results in extreme hypercholesterolemia and development of severe atherosclerotic complications within the first several decades. Cholesterol-lowering drugs are largely ineffective in patients with completely absent or nonfunctional receptors. Hence plasmapheresis is the treatment of first choice. It may be performed by simply removing plasma and replacing it with albumin or by using selective lipid absorption columns. The reported advantages of the latter treatment are the greater volumes that may be processed with less depletion of coagulation factors, immunoglobulins, and high-density lipoproteins. Columns come in many varieties; the most commonly used are disposable dextran sulfate columns. A dual column method has been developed that cannot be saturated; collected lipid is eluted from one column while the second is collecting. This system has been shown to be effective in pediatric patients.[441] Disadvantages of using columns include additional extracorporeal volume (150 to 400 mL) added to the system and some reports of adverse side effects.

Transplantation

ABO-incompatible bone marrow or solid organ transplant is most problematic when the recipient has IgM antibodies against the donor ABO type.[442] Apheresis can be used to deplete isohemagglutinins (naturally occurring anti-A, anti-B antibodies).[443] Although this approach is effective in reducing IgM titers, it often requires several daily procedures, resulting in large numbers of donor exposures.[444] Most bone marrow transplant programs have switched to depleting the donor marrow of RBCs, a one-time procedure that has not been shown to compromise engraftment. For ABO-incompatible cardiac transplantation in neonates, however, plasmapheresis, either as a separate procedure or incorporated into cardiopulmonary bypass, may be used immediately before or after transplant surgery to remove isohemagglutinins.[148] Plasmapheresis has also been used to reduce HLA antibodies in patients who are candidates for renal transplantation but who have high degrees of HLA sensitization that restrict compatible organ availability and increase the risk of hyperacute rejection.[445]

Disseminated Intravascular Coagulation

Purpura Fulminans

Plasmapheresis may be used in desperate situations. Specifically, the dramatic coagulopathy of purpura fulminans associated with meningococcal sepsis can be treated with plasmapheresis. In trials using historical controls, improved survival and correction of coagulopathy have been documented, but because the trials have no concurrent controls, it is impossible to be sure that plasmapheresis contributed to the improvement.[446]

Special Applications and Selective Adsorptions

Plasmapheresis allows the selective removal of components in plasma by additional processing of the separated plasma. The columns currently available in the United States are the previously described lipid adsorption columns. Other columns not available for clinical use in the United States use beads coated with antigen to remove a specific antibody.

Another selective-removal apheresis methodology has been developed to target the removal of some populations of granulocytes and monocytes based on their adherence to cellulose acetate beads. According to several reports from Japan, this form of granulocytapheresis is efficacious and safe in the treatment of ulcerative colitis, but the device is also not currently available in the United States.[447-449]

CONCLUSION

The addition of mechanical apheresis devices to the therapeutic armamentarium of transfusion medicine specialists has allowed for dramatic interventions in both acute and chronic disorders. The complexity of the clinical settings in which apheresis is sometimes used often makes it difficult to assess the value of apheresis-based therapies. As economic constraints continue to encroach on the application of medical technologies, it is imperative to design well-controlled studies to document the efficacy of the intervention. Consensus statements provide an opportunity to pose testable questions for interventions in multicenter trials. The involvement of pediatric transfusion medicine specialists is warranted early in the design of such trials owing to the technical complexity of the procedures and the unique requirements of pediatric patients. Producers of apheresis devices must also be mindful of these unique requirements because protocols designed for adults are not always applicable to children. Reduction in extracorporeal volume, for example, may be beneficial to adults as well as pediatric patients.

CHAPTER 37

Hematologic Manifestations of Systemic Diseases*

Rachael F. Grace

CHAPTER OUTLINE

COLLAGEN DISORDERS
Collagen Vascular Disease
Vasculitis
Connective Tissue Disorders
INFECTIOUS DISEASES
General Hematologic Signs of Infection
Hematologic Aspects of Specific Infections
CARDIAC DISEASE
Hemolysis
Acquired Coagulation Abnormalities
Platelet Abnormalities
Miscellaneous Hematologic Manifestations of Heart Disease
PULMONARY DISEASE
Cystic Fibrosis
Idiopathic Pulmonary Hemosiderosis
Pulmonary Hemosiderosis from Other Causes
Hematologic Findings in Other Pulmonary Disorders
RENAL DISEASE
The Red Blood Cell
The White Blood Cell
Coagulation Abnormalities
Platelet Abnormalities
GASTROINTESTINAL DISEASE
Diseases of the Gastrointestinal Tract
Disease of the Pancreas
Diseases of the Liver
ENDOCRINE DISORDERS
Thyroid Gland
Adrenal Gland
Pituitary Gland
Other Endocrine Disorders
Diabetes Mellitus
METABOLIC DISEASES
Disorders in Lipid Metabolism
Other Metabolic Disorders
NEUROLOGIC AND PSYCHIATRIC DISORDERS
Neuroacanthocytoses
Anorexia Nervosa
CUTANEOUS DISEASES
Eczema and Psoriasis
Hereditary Hemorrhagic Telangiectasia
Mast Cell Disease
PREGNANCY
Anemia of Pregnancy
Thrombocytopenia and Pregnancy
Disseminated Intravascular Coagulation and Pregnancy
Sickle Cell Disease and Pregnancy
Inherited Bleeding Disorders and Pregnancy
Pregnancy and Thrombosis
Inherited Hypercoagulable States and Pregnancy
Antiphospholipid Antibody Syndrome and Pregnancy
TOXINS AND OTHER INSULTS
Alcohol and Hematopoiesis
Thermal Injury
Venoms

Evaluation of almost any patient who seeks medical attention, particularly in a hospital setting, includes the obligatory complete blood cell count. The vast majority of these patients do not have a primary hematologic problem. However, there are many pathophysiologic paradigms that have secondary effects on hematopoiesis and/or the coagulation system. One of the most common examples of these effects includes the anemia of chronic disease or inflammation, which is associated with a wide variety of acute and chronic illnesses, including cancer, collagen vascular disease, severe tissue injuries, renal failure, and infectious processes.[1] A detailed discussion of the anemia of chronic disease can be found in Chapter 11.

---

*This chapter is modified from the original chapter written by Dr. R. Alan B. Ezekowitz and includes material written by Dr. Samuel E. Lux, IV, with his permission.

In this chapter, both an organ system and disease-specific approach is used. The goal of this chapter on the hematologic manifestations of systemic diseases is to focus on information that is not included in other sections of this book. For overlapping topics, the reader will be guided to other relevant chapters throughout the book.

COLLAGEN DISORDERS

Collagen Vascular Disease

Many of the hematologic manifestations of the various collagen vascular diseases are similar. However, the characteristics that are unique to each syndrome are emphasized in this section.

Systemic Lupus Erythematosus

Anemia. Anemia is the most common hematologic abnormality in systemic lupus erythematosus (SLE).[2,3] There are multiple causes of anemia in this disease, although the anemia of chronic disease is probably the most common (see Chapter 11).

Acquired autoimmune hemolytic anemia (AIHA) may precede the onset of active SLE. It is typically characterized by a warm-type AIHA with a serologic pattern of immunoglobulin (Ig) G plus complement on the red blood cell surface.[4] Although positive results on an antiglobulin test are common, true hemolysis is seen in less than 10% of patients.[5] Chapter 13 details the pathophysiology and management of AIHA.

Mechanical hemolytic anemia may be seen in SLE-associated thrombotic thrombocytopenic purpura (TTP). Myelofibrosis has also been described in several patients with SLE; immune complexes have been suggested but not proven to be the cause of this rare complication of SLE.[6] Aplastic anemia has been reported in association with SLE.[7]

Leukopenia. A reduction in the total white blood cell count is seen in most patients but is more common in adults than children. The leukopenia is usually caused by a combination of decreased numbers of granulocytes and lymphocytes.[8] Lymphopenia may be severe in SLE[9] and is sometimes due to IgG or IgM antilymphocyte antibodies.[10-12] The magnitude of the reduction in T cells parallels disease activity and is associated with defects in cellular immunity, as measured by skin tests of delayed hypersensitivity, blast transformation in response to mitogen (phytohemagglutinin and concanavalin A), and macrophage-inhibiting factor production.[9,13] Reduced numbers of regulatory T cells contribute to the loss of T- and B-cell tolerance in SLE.[14] Unlike T-cell function, B-cell function is increased despite the decrease in the absolute number of B cells with emergence of autoreactive B cells.[15,16] There is actually an increase in IgG-synthesizing peripheral blood lymphocytes, as well as elevated numbers of cells capable of binding native DNA and elevated numbers of IgM- and IgG-producing cells with antibody specificity against DNA antigen.[17,18] These changes in peripheral blood lymphocytes are associated with certain morphologic alterations. A strongly basophilic cytoplasm and a high nuclear-to-cytoplasmic ratio are noted in many lymphocytes believed to be “immunoblasts.”[19] On electron microscopic examination, inclusions are identified within lymphocytes that appear as undulating tubules characteristically associated with the endoplasmic reticulum.

Antibodies to granulocytes have been proposed as one mechanism for the granulocytopenia. Granulocyte antibodies and peripheral granulocyte destruction have been observed.[20] Bone marrow depression of granulocyte formation may also occur. Sera from patients with SLE can inhibit mouse bone marrow colony-forming units.[21] Qualitative abnormalities in granulocyte function have also been noted. Although several investigators have found no abnormalities in chemotaxis,[22,23] others have observed abnormal migration by the skin window technique and diminished in vitro phagocytosis.[24,25] These defects parallel the observed depressions in complement. The qualitative defects in granulocyte function may be the result of altered humoral factors rather than defects in the phagocytic cells themselves.

Thrombocytopenia. Thrombocytopenia secondary to platelet immune sensitization is the most common immune-mediated hematologic manifestation of SLE (see Chapter 34). Thrombocytopenia may be an initial manifestation of SLE, and consideration of SLE should be part of the evaluation of immune thrombocytopenia (ITP) in adults and adolescent females. Occasionally, ITP may manifest years before serologic evidence or clinical manifestations of SLE are detectable.[26] Similar to primary ITP, platelet survival is shortened and there are typically increased numbers of bone marrow megakaryocytes. The platelet antibody is commonly an IgG with a molecular mass of 150,000 to 330,000 daltons, and it binds complement.[27] ITP in patients with SLE has the same therapeutic implication as primary ITP, that is, corticosteroids or intravenous immune globulin as primary intervention, with other treatments, including rituximab and splenectomy, reserved for patients who fail these approaches.

Rarely, a qualitative defect in platelet function may also be present with an antibody that interferes with platelet aggregation.[28,29] Thrombocytopenia may be seen in association with SLE and TTP.[30]

Lupus Anticoagulant and Antiphospholipid Syndrome. Patients with SLE may also have a circulating anticoagulant in their plasma.[31,32] The antibody-anticoagulant is directed against various phospholipids involved in phospholipid-dependent anticoagulation assays.[33] Most investigators have reported that lupus anticoagulant is an immunoglobulin that may be of the IgG, IgM, or mixed IgG-IgM class.[34-37] The pathologic significance of the lupus anticoagulant and other antiphospholipid antibodies is their association with thrombosis, mainly venous, as well as miscarriages and spontaneous abortions (see Chapter 35). Among adult SLE patients, 12% to 30% have anticardiolipin antibodies and 15% to 34% have lupus anticoagulant antibodies.[38-41] The prevalence of thrombosis in pediatric SLE patients with lupus anticoagulant is not known. In adults, the prevalence of thrombosis is about 30%, with the predominant site being the legs in 66%, followed by the peripheral arteries in 10% and the cerebral arteries in 2%.[42]

The partial thromboplastin time is invariably prolonged in patients with the lupus anticoagulant and is considered to be the most sensitive screening test.[43] The inhibitor is suspected when the addition of normal plasma to the patient's plasma fails to correct the defect.[34] The prothrombin time in patients with the lupus anticoagulant is often normal or minimally prolonged because of the influence of the inhibitor. True prothrombin deficiency may occur in patients with the inhibitor, but it is rare.[44,45] Prolonged thrombin times in the absence of elevated levels of fibrin split products may occasionally be seen.[46] The exact significance of this finding is unclear.

A minority of patients have a catastrophic form of the disease.[47,48] This often fatal syndrome is defined by the clinical involvement of at least three different organs over a period of days to weeks, with pathologic evidence of multiple occlusions of large or small vessels.[49] In general, involvement of small vessels is more common in these patients, who tend to present with an acute thrombotic microangiopathy involving the kidney, lungs, central nervous system, heart, or skin, along with disseminated intravascular coagulation (DIC). The mortality rate is 30% to 50%.[48] Aggressive therapy with combinations of anticoagulants, corticosteroids, intravenous immune globulin, and plasmapheresis have been tried in anecdotal reports with varying success.

In children, the lupus anticoagulant is usually found coincidentally on routine preoperative coagulation screening.[50] In the majority of cases, this lupus anticoagulant is not associated with SLE or bleeding symptoms. In these cases, the lupus anticoagulant typically resolves spontaneously within weeks to months.[51]

Juvenile Idiopathic Arthritis (Rheumatoid Arthritis)

Anemia in rheumatoid arthritis is caused typically by both anemia of chronic disease and iron-deficiency anemia.[52] A high incidence of iron deficiency has historically been seen in children with juvenile idiopathic arthritis (JIA), because of gastrointestinal blood loss secondary to long-standing use of aspirin and nonsteroidal analgesics in the symptomatic treatment of this disease.[53] The severe inflammatory nature of this disorder makes it a model for anemia of chronic disease, a sideropenic anemia with reticuloendothelial iron overload. Iron is not only loaded inappropriately into the reticuloendothelial system but also accumulates in the involved joint, possibly playing a role in joint destruction.[54]

Microcytosis is very common in juvenile chronic forms of arthritis, with a rate of occurrence of about 40%. The degree of microcytosis relates directly to disease activity.[55] Occasionally, macrocytic anemia develops in patients with JIA.[56] Although abnormal vitamin B_{12} metabolism has been suggested as a cause, this is not seen in children. Folate metabolism may, however, be abnormal. Some children with rheumatoid arthritis have diminished plasma and red blood cell folate levels.[57] Increased folic acid plasma clearance and reduced protein binding have also been observed.[58]

A few patients have had mild shortening of red blood cell survival as a result of an extracorpuscular defect.[59] More severe hemolytic anemia is much less common than in other collagen vascular diseases. Erythroid aplasia responsive to corticosteroid therapy has been reported in a child with juvenile rheumatoid arthritis.[60] Circulating inhibitors of erythropoiesis have also been noted.[61]

Leukocytosis and neutrophilia are common during acute flare-ups of JIA; however, this is uncommon in the adult form of the disorder. Neutrophil chemotaxis may be mildly diminished.[22] Phagocytosis is normal or mildly impaired.[62] Nitroblue tetrazolium dye reduction may be increased during active phases of this disease.[63] These minimal alterations in white blood cell function do not produce any clinical disturbances. Wound healing, for example, is normal even after surgery in patients who have not been receiving high-dose corticosteroid therapy.[64] A peripheral blood eosinophil count greater than 5% has been noted in slightly more than 50% of children with JIA.[65] Some will also demonstrate basophilia and plasmacytoid lymphocytes.[66,67]

Secondary thrombocytosis is common in JIA, as part of the inflammatory response. A consumptive coagulopathy may be seen in association with systemic JIA.[68-70] Acquired circulating inhibitor to factor VIII has been described in JIA and may cause bleeding.[69] However, clinical problems related to coagulation abnormalities in this disorder are rare.[70]

Felty Syndrome

Felty[71] originally described the triad of rheumatoid arthritis, splenomegaly, and neutropenia in 1924. Whether Felty syndrome occurs with JIA is unclear. Splenomegaly is seen in about 20% of all children with JIA, especially in those with the acute extraarticular exacerbations of this disease. However, splenomegaly alone does not suggest Felty syndrome.

The etiology for the neutropenia of Felty syndrome is multifactorial. The neutropenia is not always a consequence of hypersplenism per se because only 60% of adults who undergo splenectomy experience resolution of their neutropenia.[72] In 50% of patients, a maturation arrest bone marrow pattern is demonstrated, possibly from immune humoral or cellular mechanisms. Neutropenia in association with cytotoxic lymphocytes directed against granulocyte progenitors has also been reported,[73] as have lower than normal levels of granulocyte colony-stimulating factor (G-CSF) activity.[74] The neutropenia of Felty syndrome may also be immunologic in origin, because some patients have IgG antibodies directed against neutrophils.[75,76]

The neutropenia may be associated with serious infections. Recombinant human G-CSF and granulocyte-macrophage colony-stimulating factor (GM-CSF) both effectively raise the neutrophil count in essentially all patients with Felty syndrome.[77,78] The neutrophil count decreases again once the growth factor treatment is stopped, but often it stabilizes at a level higher than it was before treatment.[77,79] The drug can be used long term and may be cost-effective in selected patients with a high incidence of infections and repeated hospitalizations.[80,81]

Methotrexate treatment in Felty syndrome can be effective in correcting the neutropenia.[82] Splenectomy may be indicated in those in whom G-CSF or GM-CSF is ineffective or rapid blood cell improvement is desired. A rise in the neutrophil count after splenectomy is experienced by 50% to 80% of patients.[77]

Vasculitis

Polyarteritis Nodosa

Microangiopathic hemolytic anemia can be associated with renal disease or hypertensive crises in polyarteritis nodosa. The hemolytic process in these circumstances parallels disease activity. Anemia of chronic disease is common in polyarteritis nodosa.

Neutropenia occurs and is associated with the presence of antineutrophil cytoplasmic antibodies.[83] Neutrophilia and eosinophilia are also common. The eosinophilia may be marked, particularly in those patients with clinically apparent pulmonary involvement.

Wegener Granulomatosis

Wegener granulomatosis, characterized by necrotizing vasculitis (particularly in the lungs and kidneys), is rare but can affect children.[84,85] The disease can also occur in the neonatal period.[86] The course of the disease is marked by fever, cough, hemoptysis, epistaxis, nasal discharge, obliteration of the nasal sinuses, and nodular pulmonary infiltrates. Renal failure may occur. A microangiopathic hemolytic anemia can develop.[87] An associated anemia of chronic disease is common.[87,88]

The white blood cell count is elevated, often coupled with an eosinophilia.[89] The disease is characterized by marked thrombocytosis.[87] Autoantibodies directed against cytoplasmic components of neutrophil granulocytes and monocytes have been described as a disease-specific marker for Wegener granulomatosis.[90,91]

Connective Tissue Disorders

Bleeding and bruising are common manifestations of connective tissue disorders related to fragility of capillaries and perivascular connective tissue rather than disorders of clotting or platelet function.[92] Primary hemostasis depends on the interaction of the vessel wall, platelets, and the clotting cascade. In connective tissue disorders, the connective tissues of the skin, subcutaneous tissue, and blood vessel wall have increased fragility, which portends increased bruising and bleeding. Laboratory evaluation for disorders of platelet aggregation and clotting factors is typically normal. Genetic counseling is recommended when a connective tissue disorder is suspected.

Ehlers-Danlos Syndrome

Most Ehlers-Danlos subtypes are caused by mutations in fibrillar collagens. The elastic tissue defects result in an increased bleeding tendency. Different forms of Ehlers-Danlos have been associated with platelet and coagulation defects, including disorders of platelet aggregation and factor deficiencies.[93-97] It is not clear whether these hematologic defects are sporadic associations in individual patients or true associations with the subtypes of Ehlers-Danlos.

In Ehlers-Danlos syndrome, the bleeding symptoms are typically easy bruising, gingival bleeding, prolonged bleeding with surgical or dental procedures, and menorrhagia. Other common clinical findings include skin hyperextensibility, “cigarette paper–like” scars, and joint hypermobility. The vascular Ehlers-Danlos syndrome, type IV, is an autosomal dominant disorder caused by mutations in the collagen type III alpha 1 *(COL3A1)* gene. Type IV Ehlers-Danlos is associated with small and large vessel bleeding, including arterial bleeding, and spontaneous ruptures of the bowel, uterus, and lungs. Nonemergent surgical interventions are to be avoided in these individuals owing to the high risk for perisurgical bleeding and complications. With serious bleeding in Ehlers-Danlos syndrome patients, efficacy of desmopressin and of factor VIIa has been reported.[98-100]

Other Inherited Connective Tissue Disorders

Marfan syndrome is not associated with fragility of capillaries or small to medium-sized arteries or veins. However, many Marfan syndrome patients report easy bruising, which has not been explained. A defective fibronectin has been proposed as the cause of the hypermobility and platelet dysfunction in some patients.[101] Easy bruising has also been reported in individuals with osteogenesis imperfecta.

Scurvy

Ascorbic acid functions as a cofactor, enzyme complement, cosubstrate, and antioxidant for a wide variety of metabolic processes.[102] Vitamin C is involved in reactions involving iron, copper, vitamin E, and folic acid. Deficient intake of ascorbic acid results in impaired collagen synthesis, mitochondrial fatty acid transport, and synthesis of neurotransmitters.[102-104] Although scurvy is uncommon in developed countries, certain patient subpopulations remain at risk for this type of nutritional deficiency, such as those with neurologic impairment, psychiatric disease, alcoholism, small bowel disease, and iron-overload disorders associated with vitamin C renal wasting.[105-108] Scurvy occurs when vitamin C has been eliminated from the diet for at least 3 months. Hematologic symptoms of scurvy arise mainly from defective collagen synthesis and include gingival bleeding, subperiosteal hemorrhage with painful joint bleeding, and organ hemorrhage. Scurvy is associated with a multifactorial anemia related to bleeding, dietary deficiencies, oxidative hemolysis, and altered metabolism of iron and folate.[109,110] Other manifestations include poor wound healing, defective dentine formation, tooth and hair loss, and bony changes. The symptoms of scurvy, including the bleeding manifestations, rapidly respond to enteral vitamin C supplementation.

INFECTIOUS DISEASES

General Hematologic Signs of Infection

Red Blood Cell Disturbances

The anemia of chronic disease is common to all infections. Even common childhood infections, especially those associated with inflammation, will cause a decline in hemoglobin concentration. During active inflammation, the hemoglobin concentration declines about 13%, usually within 1 week, followed by an increase of nearly 25% during resolution of the active inflammation.[111] The actions of hepcidin probably deprive microorganisms of iron, which is an essential nutrient for microbial replication, and may be a component of host immunity against infection.[112] Serum levels of iron decrease after a bacterial challenge, and the lactoferrin released from stimulated granulocytes is a conduit for this iron to return to reticuloendothelial cells. Many examples of bacterial pathogenicity being dependent on iron availability (e.g., *Neisseria gonorrhoeae, Neisseria meningitidis*) support the hypothesis that the anemia of infection is the body's compromise in an attempt to deprive invading microorganisms of iron.[113,114]

Although some infections, particularly viral ones, such as parvovirus, cause transient bone marrow aplasia or selective erythroid aplasia, anemia from this cause is rare because of the long life span of red blood cells. In contrast, patients with chronic hemolytic anemias may experience a rapid decrease in hemoglobin concentration or an "aplastic" crisis during viral and some bacterial infections.

Severe hemolytic anemia may be observed in certain types of infections. Clostridial infections may result in a high titer of hemolysins and cause severe anemia. A similar severe anemia may result from sepsis related to other bacterial organisms, including staphylococci, streptococci, pneumococci, and *Haemophilus influenzae*.[115] Immune hemolytic anemia mediated by a cold agglutinin may be observed with *Listeria* and *Mycoplasma* infections[116] and occasionally with infections by other organisms such as Epstein-Barr virus.

Many viral illnesses may be associated with what appears to be a mild hemolytic anemia for which no pathologic mechanism has been defined. The most common morphologic finding in these circumstances is poikilocytosis. Certain viruses, such as most strains of influenza virus, contain neuraminidase activity, which is, at least theoretically, capable of affecting the sialic acid content of the red blood cell membrane. Whether this plays any significant role in the hemolysis associated with some viral diseases is not known.

Many congenital infections, including cytomegalovirus, herpes simplex, rubella, toxoplasmosis, and syphilis, produce profound hemolytic anemia in the neonatal period, even though these same agents may not significantly alter red blood cell survival at other times of life.

White Blood Cell Disturbances

The white blood cell count may be normal, low, or high with infection. Viral illnesses may be associated with leukocyte counts lower than 5000 cells/mm^3, although bacterial diseases of certain types or overwhelming sepsis of any type may also cause leukopenia. The most common viral illnesses associated with leukopenia are infectious hepatitis, infectious mononucleosis, rubella, measles, and, occasionally, influenza. Of the bacterial infections, shigellosis may produce leukopenia with a marked increase in band cell forms. Sepsis caused by meningococci, pneumococci, staphylococci, and a few other bacterial pathogens may also cause leukopenia.

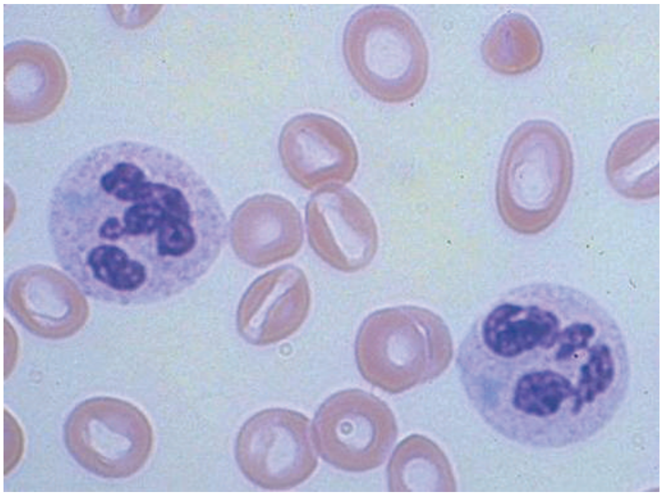

Figure 37-1 Döhle bodies.

Neutrophilia, with or without an increase in band cell count, is a common result of bacterial infection. White blood cell and neutrophil counts do not differ between children of different races with bacteremia.[117] Occasionally, viral illness also initially will be manifested as neutrophilia. A variety of morphologic changes may appear in the neutrophils of patients with infection. Döhle bodies (Fig. 37-1), which are pale blue cystlike inclusion bodies usually located in the periphery of the cytoplasm of neutrophils, may appear in bacterial infections.[118] They are occasionally associated with viral illness but are also commonly seen in patients with burns, massive trauma, and cancer, as well as in pregnancy and after the use of cyclophosphamide.[118] In addition, Döhle bodies are seen in the May-Hegglin anomaly.[119] Increased size of neutrophil granules ("toxic granulation") may be found in both bacterial and viral illnesses, as well as in many of the other disorders associated with the presence of Döhle bodies. Vacuolization of the cytoplasm of neutrophils is the next most common morphologic abnormality of neutrophils in patients with significant bacteremia. In overwhelming sepsis, the organisms are frequently evident in the vacuoles of the polymorphonuclear cells. In a study of the neutrophils of patients with bacteremia, Zipursky and associates[120] found toxic granulation, Döhle bodies, and vacuolization in 75%, 29%, and 24%, respectively, of the patients studied.

Increased neutrophil alkaline phosphatase activity and nitroblue tetrazolium dye reduction may also occur,[121,122] but neither of these characteristics is specific for bacterial infection. Infections may be associated with development of the Pelger-Huët anomaly (Fig. 37-2), in which granulocytes and eosinophils have one or two lobes per nucleus and assume a round, dumbbell, or peanut shape.[123]

In neonates, especially those born prematurely, an increase in total white blood cell or mature neutrophil counts may not be seen in the presence of infection. In fact, a decrease in the neutrophil count often occurs. The

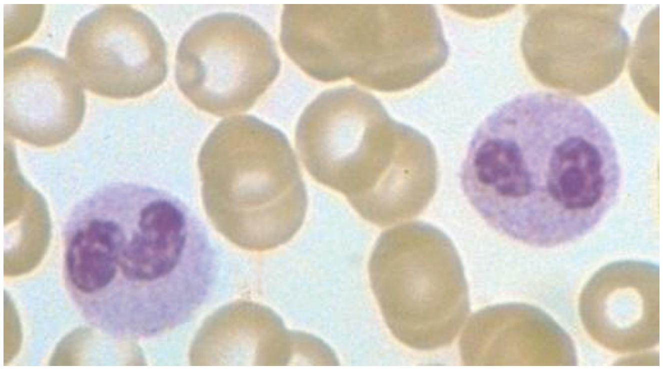

Figure 37-2 Pelger-Huët anomaly.

most helpful signs of septicemia in this age group are an increase in the band cell count and the presence of toxic granulations and Döhle bodies.[120,124]

Leukocytosis may result from lymphocytosis. The most common infections producing the greatest increases in lymphocyte counts are infectious mononucleosis, cat-scratch disease, and pertussis. Many other viral illnesses, such as cytomegalovirus, rubella, mumps, and hepatitis, may also cause an increase in the lymphocyte count. Lymphopenia of T lymphocytes is a common finding after measles infection.[125]

Eosinophilia may reflect the presence of parasitic infections. In the United States, the most common cause of marked elevations in eosinophil counts is *Toxocara* infestation, which is often accompanied by high titers of isohemagglutinins. Other parasites commonly causing eosinophilia include organisms belonging to *Trichinella, Echinococcus, Filaria, Strongyloides, Schistosoma, Enterobius,* and *Ancylostoma* and tapeworms other than *Echinococcus.* Allergic sensitization to mites may cause eosinophilia, as well as fungal infections, especially aspergillosis.[126] Eosinophilia is not specific for infestation. Marked degrees of eosinophilia may occur in association with prematurity. An absolute eosinophilia may be expected in about 75% of low-birth-weight infants.[127] In some, the eosinophilia is marked (3000 cells/mm^3) and the maximal increase seems to occur at about the time that birth weight is regained, although this is not true in all infants.[128]

Monocytosis is occasionally reported with specific infections, especially tuberculosis, syphilis, and subacute bacterial endocarditis. Monocytosis is often noted early in the course of many infections and again on recovery, particularly if it is associated with granulocytopenia.

Basophilia is rarely seen in infection but has been reported with tuberculosis, influenza, and hookworm infestation.[129]

Clotting Abnormalities and Thrombocytopenia

DIC may be triggered by infectious processes. Of the infectious causes, gram-negative septicemia is probably most common. *Meningococcus, Escherichia coli, Proteus, Pseudomonas, Aerobacter,* and *Klebsiella* are among the most common etiologic agents recovered from the bloodstream.[130,131] Gram-positive septicemia can cause a similar picture. The most common offender is *Streptococcus pneumoniae,* especially in asplenic individuals. Other gram-positive agents causing DIC include *Staphylococcus aureus,* other streptococcal species, and *Clostridium.* A wide range of viral infections may cause a consumptive coagulopathy that often leads to purpura fulminans. Among the most common agents are those that cause infectious hepatitis, measles, rubella, varicella, and infectious mononucleosis. Less common causes of DIC are severe mycoplasmal, rickettsial, and malarial infections.

Thrombocytopenia occurring separately from a true disseminated consumptive process is quite common in many infectious processes, especially in association with infectious mononucleosis, cytomegalovirus, rubella, measles, gram-negative bacteremia, and rickettsial diseases. Congenital viral infections and congenital syphilis and toxoplasmosis, if clinically apparent, are almost invariably associated with increased platelet turnover with or without thrombocytopenia. Pediatric immune thrombocytopenia is commonly associated with viral infections.[132] Immune thrombocytopenia may also occur after immunization with the measles, mumps, and rubella vaccine.[133] Corrigan found that thrombocytopenia without consumptive coagulopathy is an extremely common finding in infants and children with septicemia.[134] In contrast, thrombocytosis is often present during the active phases of infectious processes. The platelet distribution width and mean platelet volume may be helpful in predicting whether the thrombocytopenia is due to infection. In the late neonatal period, thrombocytopenia associated with an infection dramatically increases the mean platelet volume and platelet distribution width as determined by electronic counting equipment.[135]

Bone Marrow Abnormalities

The bone marrow frequently contains clues as to the source of infectious diseases. Histoplasmosis (Fig. 37-3), tuberculosis, kala-azar, *Salmonella typhi,* and *Candida* (Fig. 37-4) all have been identified in marrow macrophages. Marrow granulomas may be a marker of disseminated tuberculosis or histoplasmosis (Fig. 37-5).

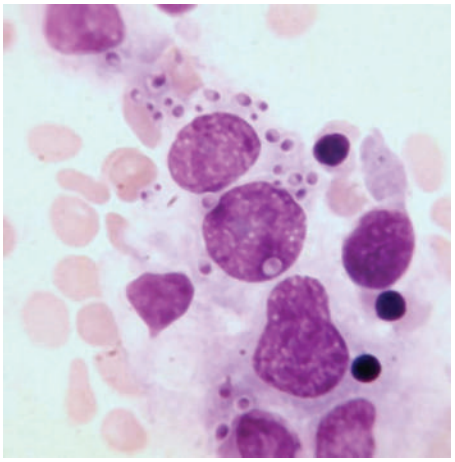

Figure 37-3 Histoplasmosis in the bone marrow.

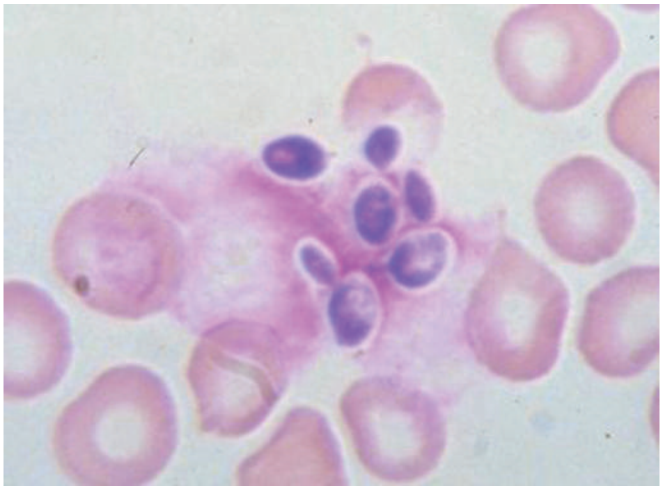

Figure 37-4 *Candida albicans.*

Histoplasmosis, tuberculosis, brucellosis, and *Salmonella* can be successfully cultured from the marrow aspirate.

Hematologic Aspects of Specific Infections

Bacterial Infections

Clostridial Sepsis. *Clostridium perfringens* septicemia is seen in a variety of clinical situations but must particularly be considered in patients with penetrating wounds, septic abortions, peritonitis after a perforated viscus, or cholecystitis or cholangitis; in immunosuppressed patients with gastrointestinal or hematologic malignancies; and in neonates with necrotizing enterocolitis.[135-151] In patients with clostridial sepsis, severe, rapidly progressive intravascular hemolysis and microspherocytosis may occur (Fig. 37-6).[135,137,143,150,151] Hemolysis of the entire red blood cell mass has been reported.[135,142,145,152-154]

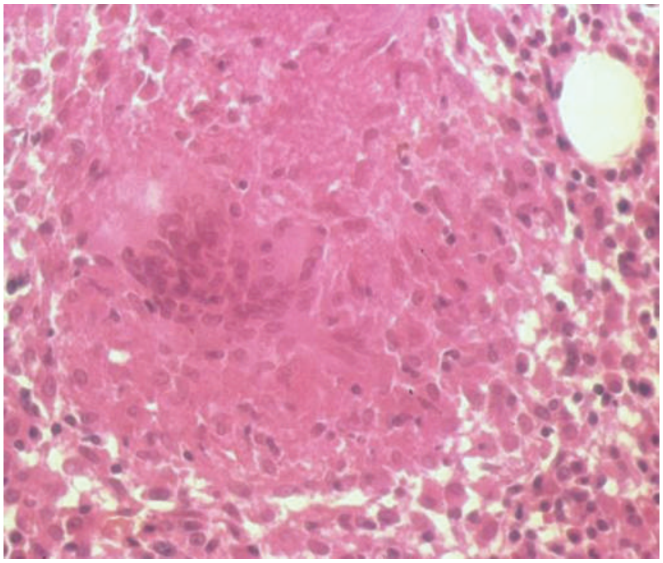

Figure 37-5 Bone marrow granuloma.

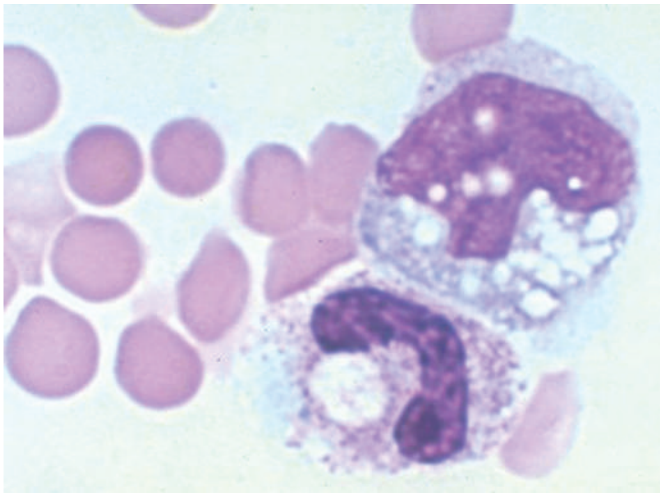

Figure 37-6 Peripheral blood in *Clostridium perfringens* septicemia demonstrating microspherocytes, neutrophils with toxic granulation, vacuolization, and Döhle bodies and erythrophagocytosis.

Complications include shock, acute renal failure, and death. Transfusion therapy may be ineffective. Antibiotics and hyperbaric oxygen occasionally have been used successfully to treat clostridial infections.[139,144,145]

The mechanism of red blood cell damage is uncertain and may vary between patients. The bacteria produce several hemolytic toxins including α-toxin, a 43-kD protein that contains an NH_2-terminal phospholipase domain and a COOH-terminal domain required for hemolysis, and θ-toxin, a 54-kD cholesterol-binding protein that aggregates and forms membrane pores leading to colloid osmotic hemolysis.[144,155-160] α-Toxin appears to induce hemolysis through the activation of sphingomyelin metabolism.[160-162] *C. perfringens* contains a neuraminidase that cleaves terminal sialic acids from red blood cell glycoproteins in some patients.[163] The underlying galactose residues form the Thomsen-Friedenreich cryptoantigen (or T antigen). Anti-T antibodies are present in almost all adult plasma; thus T-antigen activation can lead to significant hemolysis.[135,136,138,164] In infected infants and children who lack T antibodies, transfusion may lead to massive hemolysis and death. Rarely, T-antigen activation may precede the intravascular hemolysis, leading to early detection of clostridial sepsis and lifesaving therapeutic intervention.[135]

Pertussis. Pertussis may cause a marked increase in the white blood cell count, with elevations to 40,000 cells/mm^3 or higher, most of which are due to an increase in the lymphocyte count. Marked leukocytosis has been associated with a more severe course.[165] Hyperleukocytosis with white blood cell counts greater than 100,000 cells/mm^3 has been associated with the presence of immature leukocytes and obstruction in the pulmonary microcirculation. Successful leukoreduction has led to clinical improvement in a number of young infants with severe pertussis.[166,167]

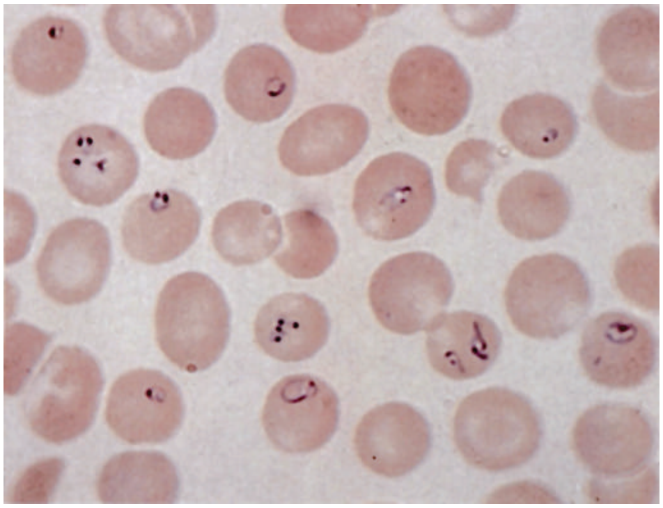

Figure 37-7 Babesiosis in the peripheral red blood cells.

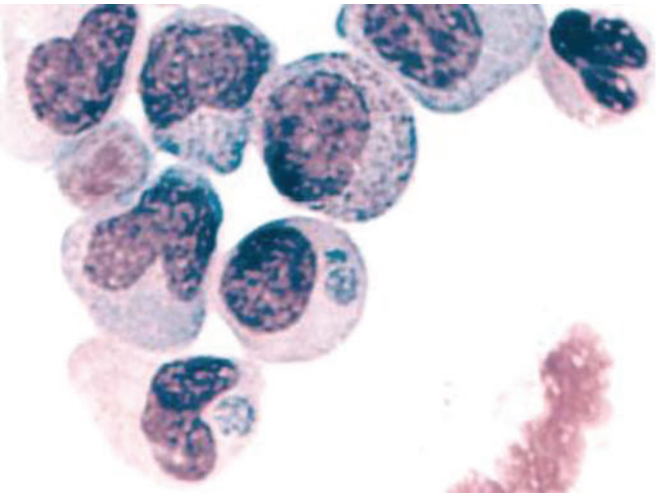

Figure 37-8 Intramonocytic morula in human monocytic ehrlichiosis.

Babesiosis. In healthy individuals, a mild hemolytic anemia is caused by *Babesia microti* and *Babesia divergens* microorganisms.[168,169] Occasional cases of combined *B. microti* babesiosis and Lyme disease are described, attributable to the shared geographic locale of the tick vectors for these diseases.[170] The disease can also be acquired by transfusion.[171] Babesiosis is not life threatening except in asplenic subjects in whom the parasitized red blood cells are not contained.[168,169,172] Then, the infection can be rapidly progressive and life threatening. In extreme cases, nearly all the red blood cells may be parasitized (Fig. 37-7).[173] Patients may have malaise, headache, fever, shaking chills, profuse sweating, jaundice, and dark urine. There may be intravascular hemolysis and, occasionally, pancytopenia and hemophagocytosis.[174,175] Diagnosis is made by finding the parasites in blood smears or by serologic tests or amplification of parasitic DNA using the polymerase chain reaction (PCR) assay. Current treatment of symptomatic cases is quinine plus clindamycin, but treatment failures have been reported in asplenic patients. Exchange transfusion may reduce the parasite load and be beneficial.[173]

Anaplasmosis (Ehrlichiosis). A variety of hematologic manifestations are found in infections with *Ehrlichia chaffeensis,* the causative bacteria of human monocytic ehrlichiosis (HME, Fig. 37-8), and *Anaplasma phagocytophilum,* the causative bacteria of human granulocytic anaplasmosis (HGA, Fig. 37-9)).[176] The disease is transmitted through tick bites, typically through the Lone Star tick or *Ixodes scapularis,* the shared tick vector of Lyme disease and babesiosis.[177] Transmission has also been reported through blood transfusions.[178] Symptoms are variable but are most severe in immunocompromised individuals. The obligate intracellular bacteria grow within membrane-bound vacuoles in leukocytes. General symptoms can include fever, headache, rash, and neurologic symptoms.[179,180] Thrombocytopenia and leukopenia are common, often with both lymphopenia and neutropenia.[181] Lymphopenia can be followed by an atypical lymphocytosis in the later stages of disease. Intraleukocytic morulae detected on review of the peripheral blood smear or buffy coat can be seen in up to 50% to 70% of infected individuals.[181] Diagnosis can also be made through serologic tests or PCR assay. Doxycycline is the treatment of choice; however, rifampin has been reported to be effective in young patients.[182]

Mycobacteria. Tuberculosis produces a variety of hematologic abnormalities. Leukemoid reactions mimicking myeloproliferative disorders are common.[183] Bone marrow involvement in miliary tuberculosis may result in a leukoerythroblastic pattern with teardrop-shaped red blood cells, nucleated red blood cells, and myeloblasts apparent on the peripheral blood smear.[184] Bone marrow biopsy may show evidence of granulomas. Monocytosis is common, and thrombocytopenia and pancytopenia have been reported.[185]

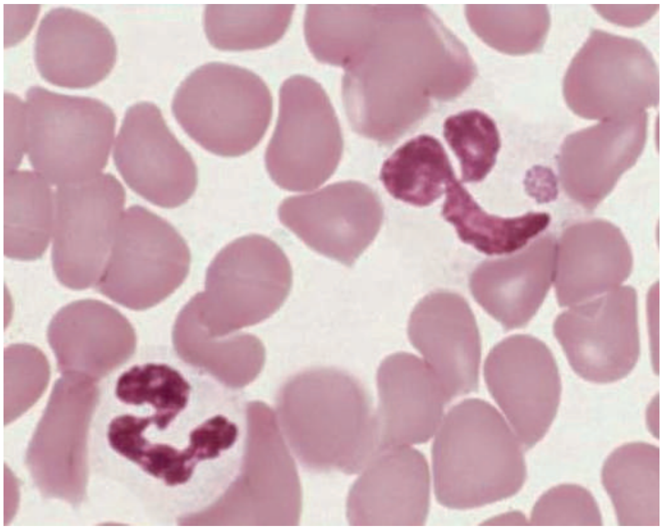

Figure 37-9 Morula-infected neutrophil in human granulocytic anaplasmosis.

Viral Infections

Parvovirus B19. Parvovirus B19, the cause of fifth disease (erythema infectiosum) in children, infects and kills early erythroid progenitors bearing the P blood group antigen.[186] This infection, which is discussed in Chapter 6, is not clinically significant unless the infection occurs in the setting of chronic hemolytic processes such as sickle cell disease or hereditary spherocytosis, or in patients with compromised immunity.[187] In these situations, life-threatening red blood cell aplasia or even pancytopenia may be caused by this virus. The infection typically presents as fever, vomiting, and abdominal pain, along with pallor, fatigue, and other symptoms of anemia.[188] Sometimes multiple family members are affected simultaneously. Parvovirus B19 infections are often associated with mild neutropenia or thrombocytopenia, and isolated cases of transient pancytopenia, hemophagocytosis, and transient myelodysplasia are reported.[189-192] The virus is a particular danger to pregnant women because it can cause fetal death due to anemia and nonimmune hydrops fetalis.[193]

Infectious Mononucleosis. Infectious mononucleosis is caused by the Epstein-Barr virus (EBV) and historically associated with the triad of (1) the classic clinical picture, (2) atypical lymphocytosis, and (3) positive results on a heterophil antibody test.[194] Serologic testing for EBV is now often used in addition or instead of the heterophil antibody test to confirm acute infection.

Epidemiology. EBV infection is acquired at an early age in lower socioeconomic groups. In economically privileged children, infection is often delayed until adolescence and young adulthood. About 40% of American children are seropositive for EBV by 5 years of age.[195-197] In a report from the U.S. Military Academy at West Point, 63.5% of entering cadets had EBV antibody, indicative of previous infection.[198] During the college years, the infection rate among susceptible individuals is 12% to 15% per year.

The pattern of infection in different groups of susceptible persons is probably best explained by transmission of this virus in throat secretions. EBV is present in the saliva of most patients with infectious mononucleosis, in up to 20% of healthy persons with EBV antibodies, and in 50% or more of seropositive patients receiving immunosuppressive drugs. The ease with which EBV is recovered from the oral secretions of persons with primary or reactivated EBV infection suggests that a cell type that freely permits EBV replication exists in the oropharynx. The oropharyngeal epithelial cell may be the target cell type that is productively infected in infectious mononucleosis.[199] Transmission requires intimate contact. Intrafamilial spread, however, does occur frequently, and, in this setting, an incubation period of 4 to 6 weeks has been demonstrated.[200] Another possible route of transmission of EBV is transfusion through white blood cells.

Clinical Manifestations. The classic clinical manifestations of infectious mononucleosis are generally seen only in adolescents and young adults. Younger children rarely exhibit the typical findings of this disease, and most generally have only a mild viral respiratory illness.[195-197]

The onset of typical illness is usually a subtle prodrome consisting of fatigue, malaise, sweating, feverishness, and anorexia. Headache, nausea, and vomiting are seen frequently. The most common symptom during this period is a sore throat, which begins slowly and increases in intensity over a 1-week period. The usual findings of infectious mononucleosis then follow (Table 37-1). The

TABLE 37-1 Approximate Rate of Occurrence of Various Signs and Symptoms of Infectious Mononucleosis in Young Adults

Symptom or Sign	%
Adenopathy	100
Malaise and fatigue	90-100
Fever	80-95
Sweats	80-95
Sore throat, dysphagia	80-95
Pharyngitis	65-85
Anorexia	50-80
Nausea	50-70
Splenomegaly	50-60
Headache	40-70
Chills	40-60
Bradycardia	35-50
Cough	30-50
Periorbital edema	25-40
Palatal enanthema	25-35
Liver or splenic tenderness	15-30
Myalgia	12-30
Hepatomegaly	15-25
Rhinitis	10-25
Ocular muscle pain	10-20
Chest pain	5-20
Jaundice	5-10
Arthralgia	5-10
Diarrhea or soft stools	5-10
Photophobia	5-10
Rash	3-6
Conjunctivitis	5
Abdominal pain	5
Gingivitis	3
Pneumonitis	3
Epistaxis	3

From Finch SC: Clinical symptoms and signs of infectious mononucleosis. In Carter RL, Penman HG, editors: Infectious mononucleosis, *Oxford, 1969, Blackwell Scientific, p. 35.*

course of fever often follows a specific pattern, with no temperature elevation in the morning but daily afternoon or evening peaks of 38.3° C to 39.4° C (101° F to 103° F). Occasionally, higher temperatures are observed. The fever usually lasts about 2 weeks.

Lymphadenopathy is seen in all patients. Symmetric, moderately enlarged, discrete, slightly tender nodes, especially in the posterior cervical region, are most characteristic. Adenopathy is common in the axillary, epitrochlear, and inguinal areas. The nodes are not matted and do not show signs of heat, redness, or fluctuation. Rarely, enlargement of the mediastinal glands constitutes the only evidence of adenopathy and may be confused with a lymphomatous process.

Splenomegaly occurs in more than 50% of patients with infectious mononucleosis. The spleen is usually just barely palpable but on rare occasion may be quite large. It is smooth, soft to firm, and sometimes slightly tender. In some patients, splenomegaly persists for months, but the most common situation is resolution by 2 to 3 weeks after onset of the illness.

Hepatomegaly occurs in about 20% of patients, and clinical jaundice is seen in 10%. The jaundice is invariably mild. Despite the low rate of occurrence of apparent hepatic dysfunction, virtually all patients with infectious mononucleosis demonstrate abnormal liver enzyme levels. Except in rare patients with acute liver failure, the hepatitis associated with this illness is self-limited. There is no evidence that chronic liver disease or cirrhosis results from infectious mononucleosis.

Rashes occur occasionally, and their manifestation follows no particular pattern. The rash may be a diffuse, faint, erythematous or maculopapular eruption, or it may be urticarial, scarlatiniform, petechial, or herpetiform. In general, the rashes of infectious mononucleosis have no unique features and are of little or no help for diagnosis. Circulating immune complexes and complement sequence activation occur only when rashes are present.[201] If ampicillin is administered to patients with infectious mononucleosis, a rash will develop in 69% to 100%.[202] Other penicillins may cause this response but less often. This rash is not an allergic reaction, and these antibiotics may be administered subsequently without ill effect.

Only a few patients with infectious mononucleosis have no pharyngitis. Almost all demonstrate hyperplasia of the pharyngeal lymphoid follicles. The presence of an exudate is common, and membrane formation occurs frequently. The inflammation may be severe enough to cause respiratory obstruction. Peritonsillar abscesses may complicate the course of the illness.[203] A palatal enanthema is seen in about a third of patients and consists of crops of sharply circumscribed petechiae, symmetrically distributed at the junction of the soft palate. Unfortunately, such petechiae are not specific for infectious mononucleosis and have been described in rubella and other viral disorders. In fact, the entire pharyngeal manifestation of infectious mononucleosis is clinically indistinguishable from that of streptococcal disease.

Periorbital edema is not rare and occasionally leads to the erroneous suspicion that renal disease or hypoproteinemia is present. The edema is self-limited and lasts only a few days.

TABLE 37-2 Reported Complications of Infectious Mononucleosis

Type of Complication	Diagnosis or Description of Abnormalities
Neurologic	Bell palsy, cerebellar syndrome, encephalitis, encephalomyelitis, encephalomyelopathy, Guillain-Barré syndrome, meningitis, meningoencephalitis, myelitis, optic neuritis, peripheral neuritis, psychosis, radiculoneuritis, ataxia, positive Babinski sign, coma, convulsions, diplopia, extraocular palsy, facial diplegia, hemiplegia, hyperesthesia, meningismus, mental confusion, nystagmus, papilledema, psychotic reaction, ptosis, respiratory paralysis, positive Romberg sign, seizure, status epilepticus, scotomas
Cardiac	Electrocardiographic changes, myocarditis, pericarditis
Ocular	Conjunctivitis, diplopia, cyclic edema, hemianopia, lacrimal pericyclitis, nystagmus, optic neuritis, ptosis, retinal edema, retinal hemorrhage, retroorbital pain, scotomas, uveitis
Respiratory	Laryngeal obstruction, peritonsillar abscess, pharyngeal edema, pleural effusion, pleuritis, pneumonitis
Hematologic	Acquired hemolytic anemia, agranulocytosis, eosinophilia, fibrinolysis, pancytopenia, splenic rupture, thrombocytopenia
Digestive	Esophageal varices, gingivitis, hepatic dysfunction, hepatic necrosis, jaundice, melena
Renal	Hematuria, hemoglobinuria, nephritis, nephrotic syndrome, porphyrinuria, proteinuria
Other	Bullous myringitis, endocervicitis, orchitis, otitis media, pancreatitis, porphyria, rashes

From Finch SC: Clinical symptoms and signs of infectious mononucleosis. In Carter RL, Penman HG, editors: Infectious mononucleosis, *Oxford, 1969, Blackwell Scientific, p. 35.*

Complications. Much attention is paid to the complications associated with infectious mononucleosis, although their overall occurrence is low (Table 37-2). Hematologic complications of infectious mononucleosis include disturbances resulting in anemia, granulocytopenia, thrombocytopenia, and occasional coagulation defects. The rate of occurrence of these hematologic abnormalities is shown in Table 37-3.

AIHA can occur with EBV infection and developed in approximately 3% of West Point cadets with infectious mononucleosis.[198] When hemolysis does occur, it usually begins 1 to 2 weeks into the course of the illness. The majority of occurrences terminate in less than 1 month, and chronic hemolysis is rare. Although usually mild, hemolysis occasionally occurs rapidly and can then result in severe anemia. Jenkins reported the first instance of

TABLE 37-3 Infectious Mononucleosis—Laboratory Features

hemolytic anemia in infectious mononucleosis that was mediated by the temporary induction of a high-thermal amplitude cold agglutinin of anti-i specificity.[204,205] Since then, several series have verified the high incidence of anti-i antibody as the cause of immune-mediated hemolysis in infectious mononucleosis. It should be noted that although hemolysis is not common in infectious mononucleosis, the presence of anti-i is seen in as many as 50% of all patients. Not all instances of immune hemolysis in infectious mononucleosis are caused by anti-i antibodies. Anti-N antibodies have also been reported, and in some patients the nature of the antibody has not been identified.[206]

Aplastic anemia has been reported to follow the onset of infectious mononucleosis.[207] Aplastic anemia caused by EBV infection has also been reported after bone marrow transplantation.[208] Localization of EBV in the bone marrow of some patients with aplastic anemia supports a causative role of the virus in these aplastic anemia patients.[209]

Granulocytopenia is common during the acute phase of infectious mononucleosis. It is rarely severe but, on occasion, is associated with a secondary bacterial infection.[210] Bone marrow myeloid hyperplasia with myeloid arrest is the most typical finding.[211] Spontaneous resolution is the rule.

Immune thrombocytopenia occurs rarely in infectious mononucleosis.[212] Most occurrences of thrombocytopenia are mild.[213] The signs and symptoms of severe occurrences are similar to those of primary ITP. Severe hemorrhagic complications are rare.[214] Treatment of the thrombocytopenia of infectious mononucleosis in children is guided by bleeding symptoms. Treatment approaches are similar to primary ITP with first-line therapies with corticosteroids and/or intravenous immune globulin.[215]

The incidence of the neurologic complications reported varies from 0.37% to 7.3%, depending on the series.[216] A rare occurrence in adolescence is the "Alice in Wonderland" phenomenon in which objects are visualized in a very distorted fashion, with exaggerations in size, being either too large or too small.[217,218] A transverse myelopathy characterized by a sudden onset of profound weakness of the lower extremities and urinary retention may complicate the clinical course of infectious mononucleosis.[219]

Cardiac complications are rare and occur in 1% to 6% of reported series. They usually consist of only nonspecific T-wave changes or minor conduction abnormalities. Myocarditis and pericarditis are rare. Liver function abnormalities are rarely severe, although enzyme changes are common. Primary EBV infection has been associated with a Reye syndrome–like illness.[220] Severe liver dysfunction causing death is a common complication of EBV infection in the X-linked lymphoproliferative syndrome. Hepatic dysfunction is uniformly present with this disorder at the time of death and is the cause of death in about a third of such patients.[221] An unusual manifestation of infectious mononucleosis is intense jaundice. It generally results from a combination of hemolysis and mild hepatitis.[222] Spontaneous rupture of the spleen may occur.[223]

Respiratory difficulties usually consist of upper airway obstruction. Transient interstitial infiltrations, some with effusions, have been recorded. Infectious mononucleosis should be considered in the differential diagnosis of any child with pleural effusions.[224] Renal complications of infectious mononucleosis generally consist of hematuria associated with a mild nephritis. Not all occurrences have been clearly separated from poststreptococcal glomerulonephritis. Severe rhabdomyolysis can be associated on rare occasion with EBV infection.[225] Eye findings in infectious mononucleosis are unusual but may be significant when they do occur. Severe retinochoroiditis is such an ocular complication.[226] In some patients with infectious mononucleosis, lethargy, particularly daytime lethargy, is seen for prolonged periods, often longer than a year.[227-229]

X-linked lymphoproliferative syndrome is associated with fatal or severe infectious mononucleosis, acquired hypogammaglobulinemia, and malignant lymphoma. Details about X-linked lymphoproliferative syndrome can be found in Chapter 24.

A variety of malignancies have been linked to EBV, including clonal T-cell proliferations.[230] In patients who undergo transplantation, a spectrum of lymphoproliferative diseases may occur as a result of activation of EBV. These diseases may vary from an infectious mononucleosis–like polyclonal B-cell proliferation to a monoclonal B-cell lymphoma. EBV infection can also result in a hemophagocytic syndrome.[231] The total spectrum of the rare complications and unusual syndromes associated

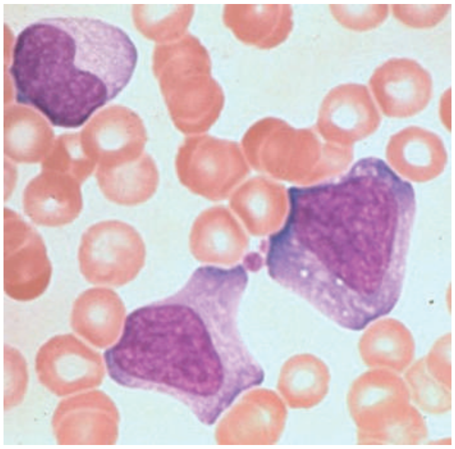

Figure 37-10 Atypical lymphocytes (Downey cells) in infectious mononucleosis.

with EBV infection have been reviewed by Timár and colleagues.[232]

Laboratory Diagnosis. Atypical lymphocytosis is the hallmark of infectious mononucleosis (Fig. 37-10). Several attempts have been made to classify these abnormal cells on morphologic grounds, the best known method being that of Downey and McKinlay.[233] However, it is clear that atypical lymphocytes cannot be easily classified into separate categories and that a spectrum of cell types exists. In general, the atypical lymphocytes of infectious mononucleosis are large, but they vary in size considerably. Their outlines are irregular, and many cells show a characteristic tendency to flow around adjacent erythrocytes. Nuclei are large and usually eccentrically located and pleomorphic, with abundant coarse chromatin and occasional nucleoli. The cytoplasm is generally abundant and typically basophilic. Cytoplasmic vacuoles may be seen. These types of cells are not morphologically specific for infectious mononucleosis and can be seen in other viral infections and after administration of a number of medications.[234]

The vast majority of atypical lymphocytes from patients with infectious mononucleosis are thymus derived.[235,236] These atypical cells possess human T-lymphocyte–specific antigens, as well as sheep erythrocyte receptors.[235] T lymphocytes appear to lack receptors for EBV, and it would appear that only B lymphocytes are infected by this virus.[236,237] A possible unifying interpretation of the role of T lymphocytes is that these cells represent an immune reaction that protects against this potentially oncogenic virus. Increased numbers of B cells are found during the first week of illness and decline to normal levels in 3 weeks. T lymphocytes reach their peak later, usually 10 to 14 days after the onset of symptoms, and remain elevated for 5 weeks.[238] There may be an early reversal of the ratio of T to B lymphocytes, with a subsequent increase in the percentage of T cells during the second through fifth weeks of illness. It is possible that both T and B cells may be "transformed" into atypical lymphocytes—B cells by infection with EBV and T cells by an immunologic response to viral antigen itself—or the B cells may respond to altered antigens on their surface. EBV-infected B lymphocytes account for only a minority of the atypical lymphocytes found in peripheral blood. In the very early stages of symptomatic illness, however, nearly 20% of all B cells in the circulation may be infected with the virus. The majority of atypical lymphocytes are T lymphocytes. Natural killer (NK) cell activity has been shown to be present during the acute phase of infectious mononucleosis. Interferons, which are inducers of NK cell activity, may have an inhibitory effect on the outgrowth of EBV-infected B lymphocytes in vitro. Significant anergy and diminished lymphocyte responsiveness in vitro to mitogens and antigens exist during the first week of illness. These lymphocyte changes are reflected in a great increase in uric acid turnover, with 55% of infected patients having serum uric acid levels of 8 mg/dL or higher.[239]

Patients with infectious mononucleosis have lymph node pathologic findings that are easily confused with lymphoma. The nodal architecture is distorted by large, dark lymphoid cells, and the capsule may be infiltrated. Reed-Sternberg cells have been reported on several occasions.[240,241] Pathologic changes are not confined to lymphoid tissue, however. Perivascular cuffing of the brain vasculature, inflammation of the liver, and inflammatory infiltration of the kidney and bone marrow have been repeatedly observed.

The heterophil antibody is so named because the antigen to which the antibody reacts is found in more than one species. The antibody, like anti-i, is an IgM macroglobulin. It agglutinates sheep red blood cells and can be removed completely from serum by preincubation with beef red blood cells but not with guinea pig kidney. Heterophil antibody titers usually increase after the third day of illness, peak at 2 weeks, and may remain positive for several months before ultimately becoming negative (unlike the antibody specific for EBV).[242] This traditional Paul-Bunnell serologic agglutination method has been largely replaced for screening purposes by the spot test, in which finely ground guinea pig kidney or beef red blood cell stroma is added to serum on a slide, followed by a drop of horse cells.[243] Results of the test are considered positive if agglutination occurs in the presence of guinea pig kidney (which absorbs out Forssman antibody but not heterophil antibody) but are negative with beef red blood cell stroma. The spot test requires only 2 minutes and is 96% to 99% accurate. Results of both the Paul-Bunnell test and the spot test are usually negative in preschool-aged children, in whom heterophil antibody production is limited.[244] This age group does produce diagnostic levels of EBV-specific antibody.

EBV is a herpeslike DNA virus. It is a relatively complex virus, and a variety of virus-associated antigens have been described.[245] Antibodies to viral capsid antigen (VCA) and early antigen (EA) are detected early after the onset of EBV-associated infectious mononucleosis.[246] Levels of antibodies to VCA reach their peak at about 3 weeks after the onset of clinical illness. Their levels decline somewhat thereafter, but they remain for life.[247] Antibodies to EA usually last 2 to 4 months. EA has two components that are differentiated by their immunofluorescent staining: "D" for diffuse and "R" for restricted

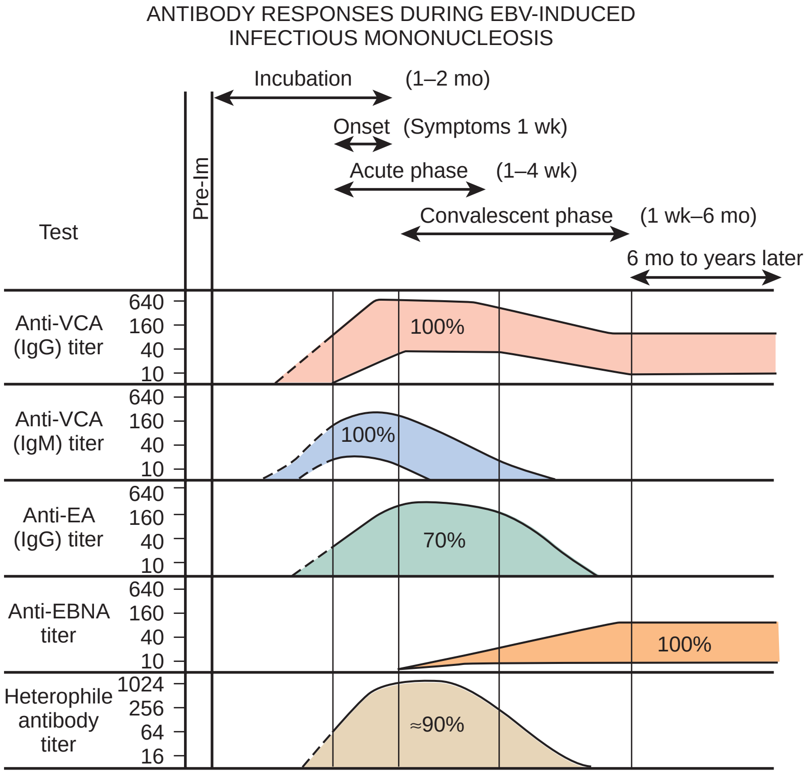

Figure 37-11 Characteristic Epstein-Barr virus–specific antibody response observed in young adults with acute infectious mononucleosis. *(Modified from Henle W, Henle GE, Horwitz CA: Epstein-Barr virus specific diagnostic tests in infectious mononucleosis.* Hum Pathol *5:551–565, 1974; and Sullivan JL: Epstein-Barr virus and the X-linked lymphoproliferative syndrome.* Adv Pediatr *30:365–399, 1984.)*

staining. A technique for determining EBV-specific IgM has been described.[248] EBV-specific IgM almost always occurs in the acute phase of infectious mononucleosis. It rarely persists more than 2 to 3 months. During this period, virus shedding from the oropharynx is easily demonstrable.[249]

Figure 37-11 shows the characteristic antibody patterns observed in young adults with EBV-induced infectious mononucleosis.[250] Before infection, no antibodies are present. During the acute phase of illness, high titers of IgM and IgG antibodies to VCA are seen. IgM antibodies are transient and disappear after 1 to 2 months. Antibodies appearing against EA disappear after a few weeks to months. Antibodies against Epstein-Barr nuclear antigen are the last to appear and are seen 1 to 2 months after the illness. In young infants, VCA IgM is found in only 60% of patients and EA antibody is identified in only 50%. The only persistent antibody response should be VCA IgG and antibodies to Epstein-Barr nuclear antigen.

Treatment. There is no evidence that bed rest or rest in general shortens the clinical course of infectious mononucleosis. Patients will determine their own level of activity. The most significant risk during acute illness is splenic rupture, but its incidence is extremely low.

Corticosteroid therapy is often used for infectious mononucleosis. Although these agents may produce improvement of symptoms, enhancement of general well-being, and reduction of fever, their use for these purposes should be restricted.[251] Less controversial is the use of corticosteroid therapy for patients with airway obstruction secondary to tonsillar hypertrophy, severe hemolytic anemia, or thrombocytopenia and bleeding.[252]

Human Immunodeficiency Virus

Epidemiology. In the early 1980s, a newly described constellation of symptoms that resulted from immune compromise and led to death from opportunistic infections and unusual malignancies was recognized.[253-255] These early descriptions of what is now known as acquired immunodeficiency syndrome (AIDS) heralded the beginning of what has become one of the major medical, public health, and social issues of our time. Identification of the human immunodeficiency virus (HIV), a retrovirus, as the etiologic agent that transmits the disease[256,257] has led to major advances in understanding the pathogenesis of AIDS. At least two types of HIV, HIV-1[256,257] and HIV-2,[258] exist; both are considered lentiviruses based on similarities in genetic composition, mechanisms of replication, and interaction with their hosts.[259] A characteristic of lentivirus infections is that they cause slowly progressive disease with an incubation period of months to years before clinical symptoms appear. The worldwide spread of AIDS has led to a plethora of information about the biology of the virus and its epidemiology and incidence projections in different countries, as well as a concerted search for effective means of prevention and treatment.

The first occurrences of AIDS in the pediatric population in the United States took place in children born to mothers infected with HIV or in children, especially neonates, who had received blood products contaminated with HIV.[260] The AIDS pandemic in Africa and, in particular, southern Africa has reached catastrophic proportions. The incidence of the disease in eastern Europe, India, and Thailand and throughout most of the Third World poses many political, social, and medical challenges, a discussion of which that is beyond the scope of this chapter.

Transmitted primarily through contact with infected lymphocytes and monocytes, HIV may be found in blood, semen, and vaginal secretions.[261,262] Isolation of the virus from 13- and 15-week abortuses, placenta, and cord blood provides strong support for intrauterine infection.[260,263-265] Maternal-fetal transfusion at delivery is another possible route of infection.[266] Postpartum transmission via breastmilk, although possible, is rare. Accordingly, in countries in which safe feeding substitutes are not readily available, breastfeeding should not be curtailed; however, in developed countries where alternatives exist, breastfeeding by HIV-infected women is discouraged.

The rate of transmission from an untreated mother to child is estimated to be about 25% based on several studies from the United States and Europe.[267-270] Transmission from mother to child can be significantly reduced by the use of antiretroviral therapy during pregnancy, labor, and the neonatal period.

Major advances in screening and testing of the blood supply in the United States after 1985 led to a reduction in the risk of receiving a contaminated single transfusion in 1988 to 1 in 250,000.[271] The first screening test is a questionnaire to exclude people who engage in high-risk activities. The next step is an enzyme-linked immunosorbent assay (ELISA) for detection of antibodies to HIV antigens. In rare individuals who are infected but seronegative, HIV can escape detection, but sensitive screening tests detect the viral genome by PCR assay.[272] Tragically, individuals with bleeding disorders such as hemophilia A and B who received clotting factors from a large donor pool for a single infusion had an increased likelihood of acquiring AIDS before modern blood screening practice and factor preparation.

Clinical Manifestations. Infection with HIV results in a spectrum of disease from an asymptomatic state to severe immunodeficiency involving multiple organ systems. The heterogeneity of symptoms is explained by the underlying pathophysiologic course in that (1) the incubation period may be weeks, months, or years; (2) the direct cytopathic effect on target cells, predominantly CD4+ lymphocytes, monocytes, and accessory cells, results in dysregulation of the immune system; and (3) the viral elimination phase that is accompanied by a host response to infection varies with the immune competence of the host. Because many children are infected congenitally, they show signs early in life and often have constitutional symptoms such as unexplained diarrhea, fever, night sweats, generalized lymphadenopathy, and hepatosplenomegaly. Failure to thrive and developmental delay are often prominent early manifestations of HIV infection in children. Susceptibility to recurrent infections by common bacterial and viral pathogens, as well as to opportunistic infections, increases the index of suspicion that the underlying disorder is AIDS. These and other manifestations of HIV infection are summarized in Box 37-1.

The hematopoietic dysfunction that is invariably associated with HIV infection results from global dysregulation of the physiologic cascades of antibody formation, coagulation and complement, and direct infection of key regulatory cells. Acute and chronic infections and therapies for the underlying disorder also affect hematopoiesis. Although for the purposes of discussion it is simpler to view these changes according to cell lineage, it should be stressed that these events rarely occur in isolation. Examination of the peripheral blood smear from the majority of AIDS patients reveals anemia and granulocytopenia and, in a third of patients, associated thrombocytopenia.[273]

Bone Marrow Findings. In several studies, the bone marrow morphologic changes in patients with AIDS were reported.[274] The most common findings were hypercellularity, lymphoid aggregates, plasmacytosis, and dysplasia. When thrombocytopenia is present, the marrow often contains adequate megakaryocytes, thus suggesting an immune mechanism of platelet destruction. The anemia and granulocytopenia appear to be related to the dysplastic bone marrow and result from ineffective hematopoiesis. Increases in reticulum and fibrosis have been reported in association with *Mycobacterium avium* infection.

Thrombocytopenia. The underlying mechanism of thrombocytopenia, which can be the initial finding of HIV infection in children, appears to be immune destruction of platelets. Several studies have identified a high incidence of cytophilic antibodies[275,276] and have highlighted concomitant complement deposition on the platelet.[277] In addition, a 25-kD platelet-associated antigen has been detected in thrombocytopenic adults and children with AIDS[278]; however, the presence of the antibody in serum does not invariably lead to thrombocytopenia. Spontaneous recovery from thrombocytopenia does occur; for instance, in one study, 8 of 25 patients with thrombocytopenia recovered.[279]

Adequate treatment of HIV infection with highly active antiretroviral therapy is the first-line approach for HIV-associated ITP and typically improves the thrombocytopenia.[280] ITP-specific treatment is considered when the platelet count decreases to less than 30,000/mL or a clinical bleeding episode is encountered. After HIV-directed treatment, first-line treatment of HIV-associated ITP includes the standard options of prednisone, intravenous immune globulin, and anti-D globulin.[281] Second-line ITP-directed treatment options can be considered with failure of the first-line agents and include splenectomy and thrombopoietin-receptor agonists.[277,282]

Anemia and Granulocytopenia. Anemia and granulocytopenia are found in most patients with AIDS and reflect, in large part, ineffective hematopoiesis. The anemia is typically normochromic and normocytic, with a low reticulocyte count and mild to severe anisocytosis and poikilocytosis. Up to 40% of patients with AIDS may

Box 37-1 **Clinical Manifestations of HIV Infection**

PRIMARY MANIFESTATIONS

HEMATOLOGIC AND IMMUNE ABNORMALITIES

Hypergammaglobulinemia
Lymphopenia (CD4+ cells decrease)
Decreased CD4/CD8 ratio
Thrombocytopenia
Anemia
Neutropenia
Drug allergies (e.g., trimethoprim in 40% to 60% of patients)

NONSPECIFIC FINDINGS (includes children with two or more unexplained findings for more than 2 months)

Failure to thrive
Hepatosplenomegaly
Generalized lymphadenopathy
Parotitis
Diarrhea (three or more loose stools per day)

NEUROLOGIC DISEASE

Loss of intellectual ability or developmental milestones
Impaired brain growth (acquired microcephaly, brain atrophy, or both)
Progressive systemic motor defects
Paresis
Abnormal tone
Pathologic reflexes
Ataxia or gait disturbance

CARDIOVASCULAR DISEASE

Cardiomyopathy
Arrhythmias

OTHER DISEASES

Hepatitis
Nephropathy (sclerosing glomerulonephritis)
Dermatologic diseases (most commonly seborrheic dermatitis)

SECONDARY MANIFESTATIONS

SECONDARY INFECTIONS

Pneumocystis carinii (now *Pneumocystis jirovecii*) pneumonia
Chronic cryptosporidiosis
Disseminated toxoplasmosis (onset after 1 month of age)
Extraintestinal strongyloidiasis
Chronic isosporiasis
Candidiasis (esophageal, bronchial, and pulmonary)
Extrapulmonary cryptococcosis
Disseminated histoplasmosis
Mycobacterial infection
Cytomegalovirus infection (onset after 1 month of age)
Coccidioidomycosis
Nocardiosis
Progressive multifocal leukoencephalopathy
Lymphocytic interstitial pneumonitis

SECONDARY CANCERS

Kaposi sarcoma
B-cell non-Hodgkin lymphoma
Primary lymphoma of the brain

From Centers for Disease Control and Prevention: Classification systems for human immunodeficiency virus (HIV) in children under 13 years of age. MMWR Morb Mortal Wkly Rep *36:225–230, 235–236, 1987.*

have positive findings on a direct Coombs test as a result of absorbed immunoglobulin. Although antibodies have been detected on the surface of granulocytes,[283,284] the mechanism for granulocytopenia appears to be suppression of bone marrow progenitors. Bone marrow from patients with HIV infection exhibits colony formation (GM-CSF and burst-forming units–erythrocyte) similar to that in HIV-seronegative control subjects when cultivated in serum from an HIV-seronegative donor. However, there is selective suppression of colony formation in bone marrow derived from a patient with HIV infection versus bone marrow from seronegative donors when cultivated in seropositive sera. This suggests that progenitor cells and progeny are able to be infected with HIV and express HIV antigens on their surface that are recognized by HIV antibodies, thus accounting for the suppression. Further support for this hypothesis comes from the demonstration of provirus in megakaryocytes from the bone marrow of patients with AIDS.[285,286]

Alloantibodies are detected in 30% to 60% of patients with AIDS in different series, with anti-i and anti-I being the most common.[283] Anti-i has also been associated with EBV and cytomegalovirus infections, both of which often coexist with HIV infection and may account for the presence of specific red blood cell antibodies. Antibodies to Le, PL, E, K, Lu, and Sd all have been found, although their relationship to the pathophysiologic course of the anemia in HIV, which in large part does not appear to be hemolytic, remains an open question.

Antiretroviral agents often causes anemia and neutropenia. Macrocytosis with 25- to 40-unit increases in mean corpuscular volume is observed in 74% of patients receiving zidovudine.[287] The macrocytosis is not usually accompanied by anemia, but when it does occur the anemia is usually mild and dose related. In a subgroup of patients, anemia caused by bone marrow suppression is observed. Neutropenia (absolute neutrophil count of 750 to 1000 cells/μL) is seen early in antiretroviral treatment and can be dose limiting.

Laboratory Diagnosis. Detection of antibodies to HIV antigens is a standard approach to the diagnosis of HIV infection. The first screen is an ELISA; positive results may be confirmed by a specific immunoblot. However, the presence of anti-HIV immunoglobulin of the IgG subclass in an infant does not necessarily indicate that the infant is infected with HIV because maternal IgG crosses the placenta and has a half-life of 28 days. In fact, persistence of maternal IgG has been detected beyond 15 months of age.[268] In contrast, several seronegative HIV-infected children have been reported.[288-290] Although IgM or IgA anti-HIV antibodies are better indicators of active infection in children because these subclasses of antibody do not cross the placenta, the sensitivity and specificity of the ELISAs for these antibody isotypes are much lower than those for IgG anti-HIV. Definitive proof of HIV infection rests with viral culture and demonstration of the provirus via the very sensitive PCR assay.[290]

Treatment. Current U.S. treatment guidelines for pediatric HIV infection advocate aggressive therapy with combination antiretroviral regimens. The goal is durable suppression of viral replication with preservation of immune function.[291] The expense and difficulty of adhering to this regimen limit access to the vast majority of infected children in the world. Prevention and education remain the most effective short-term modes of limiting the spread of AIDS.[292]

Infections in the Developing World

A detailed review of the prevalent infections in developing countries, including malaria, visceral leishmaniasis (kala-azar), schistosomiasis, trypanosomiasis, hookworm, bartonellosis, and dengue can be found in Chapter 38.

CARDIAC DISEASE

The focus of this section is on the three major hematologic complications of cardiac disease: hemolytic anemia, coagulopathy, and increased platelet turnover.

Hemolysis

A number of instances of continuing hemolysis and progressive anemia have been reported after the insertion of prosthetic valves, particularly in the aortic area.[293,294] These conditions may also occur postoperatively when intracardiac patches have been placed (the "Waring blender" syndrome). They are also being recognized as an increasing problem after endoluminal closure of the ductus arteriosus[295,296] and occasionally after repair of a ventriculoseptal defect.[297] The mechanism of such erythrocyte destruction has been related to failure of endothelialization of patches, thrombosis or perforation of prosthetic valves, and improper placement of prosthetic valves, especially when insufficiency develops at the suture lines. Erythrocyte destruction and ensuing hemolysis, however, have been described in the absence of these complications and been attributed to red blood cell mechanical trauma associated with apparently normal function of the prosthetic valve.[298,299]

Red blood cell survival studies have clearly shown that prosthetic valve and patch hemolysis is due to an extracorpuscular defect.[300] In general, hemolytic anemia results from fragmentation of the red blood cells as they are mechanically "battered" against a distorted vascular surface (Fig. 37-12).[301] In some instances, it has been postulated that the red blood cell fragmentation may be caused by contact with fibrin deposited in small blood vessels as a result of localized intravascular coagulation.[302] Most times, however, hemolysis is the result of direct mechanical trauma. Nevaril and associates[301] demonstrated that a shearing stress of 300 dynes/cm^2 causes hemolysis in vitro whereas less stress may result in deformed red blood cells morphologically similar in appearance to cells in cardiac hemolytic anemia and microangiopathic hemolytic anemia.[301]

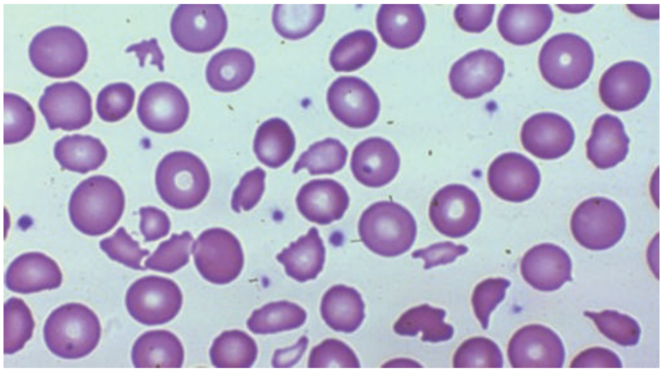

Figure 37-12 Red blood cell fragmentation due to a prosthetic heart valve.

The consequence of the process is hemolytic anemia of the intravascular type associated with hemoglobinemia and hemoglobinuria. Iron deficiency develops quickly in patients with this disorder as a result of increased loss of body iron in the form of hemosiderin, which is shed within the renal tubular cells into urine.[303,304] The onset of iron deficiency may be of clinical importance. The microcytic hypochromic cell in iron deficiency is more rigid, thereby leading to an accelerated rate of hemolysis from mechanical shearing in the microvasculature.[305] Plasma haptoglobin levels fall. Large quantities of red blood cell lactate dehydrogenase are released into serum, and a close correlation exists between the logarithm of serum lactate dehydrogenase and the half-life of chromium-labeled erythrocytes.[306] The rate of hemolysis may or may not result in anemia. If surgical correction of the defect causing hemolysis is not possible, the patient should be treated with both iron and folate, as well as red blood cell transfusion. The latter is intended to correct anemia, reduce stroke volume, and presumably reduce shear force. Sears and Crosby[307] observed that the severity of hemolysis is directly related to physical activity. This finding has been used as a test to determine whether the hemolysis is of cardiac origin because, if it is, rest also diminishes the rate of hemolysis. If the source of the problem cannot be corrected surgically, propranolol, which reduces the shearing stress between red blood cells and the vascular wall by slowing the velocity of the circulation, may be given.[308]

Mechanical injury to red blood cells may result in loss of pieces of cell membrane, with or without loss of hemoglobin. Such loss will lead to the formation of spherocytes. Consequently, in many patients with heart valve hemolysis, results of the red blood cell osmotic fragility test may be abnormal.[308] Mechanical destruction of red blood cells on abnormal surfaces of the vasculature can result in hyperkalemia. This has been reported to cause ventricular arrhythmias.[309]

Occasionally, AIHA is observed after cardiac surgery involving the placement of foreign material within the vascular system.[310] Children with 22q11.2 deletion syndrome, often with underlying congenital heart disease, are at higher risk for AIHA.[311]

Erythrocyte disturbances in children with cardiac disease must be understood in the context of compensatory states or the context of iron deficiency as a complication. For example, infants with cyanotic congenital heart disease have erythropoietin-induced compensatory polycythemia. Aortic oxygen saturation higher than 80% is usually associated with low erythropoietin titers and hemoglobin levels that will not cause hyperviscosity. Even with moderate degrees of hypoxemia, elevated erythropoietin levels are not seen; presumably, the modest elevation in hemoglobin levels provides adequate tissue oxygenation.[312-314] Infants with cyanotic congenital heart disease have higher iron requirements because of the greater hemoglobin mass. Diminished iron stores in patients with cyanotic congenital heart disease are associated with a more right-shifted oxyhemoglobin dissociation curve.[315] Most children with cyanotic congenital heart disease have evidence of mild macrocytosis. A mean corpuscular volume greater than the 90th percentile for age and sex nearly eliminates the possibility of iron deficiency.[315]

Acquired Coagulation Abnormalities

Many investigations have suggested that a coagulopathy exists in some patients with cyanotic congenital heart disease. Thrombocytopenia, low plasma fibrinogen levels, defective clot retraction, hypoprothrombinemia, factor V and VIII deficiency, and evidence of fibrin degradation products in serum have been reported.[316-320] The presence of coagulation abnormalities may correlate with the extent of polycythemia.[321] Marked derangements in coagulation often accompany surgery involving cardiopulmonary bypass.[322] Conflicting data suggest that the coagulation defects associated with cyanotic congenital heart disease must be multifactorial in origin and may be associated with both a bleeding and prothrombotic predisposition.[323] Therefore, each child should be studied individually.

Acquired von Willebrand disease is well recognized in children with congenital heart disease as well as children with aortic stenosis, with ventricular-assist devices, and on extracorporeal life support.[324-326] Mechanical destruction of high-molecular-weight multimers occurs owing to increased shear force within the abnormal cardiac anatomy. Acquired von Willebrand disease causes a mucocutaneous and/or gastrointestinal bleeding predisposition.[327] Laboratory results will demonstrate decreased von Willebrand factor collagen binding and decreased large von Willebrand factor multimers. Treatment includes supportive care with von Willebrand factor/factor VIII concentrate and/or desmopressin as a bridge to correcting the underlying contributing cardiac defect.

Repair of congenital heart disease can also be associated with coagulopathy.[328] The Fontan operation is the final surgery in the staged palliation of different forms of congenital heart disease with a univentricular heart. After the Fontan procedure, there is often increased systemic venous pressure that causes hepatic dysfunction and/or protein-losing enteropathy, both of which are associated with abnormalities of coagulation.[329]

Management of the hemostatic defects is not settled. It is agreed that they may predispose patients to postoperative hemorrhage, but they are rarely associated with preoperative clinical bleeding tendencies. Suggested management procedures have included the use of heparin[330] to lower viscosity, erythrocytapheresis with plasma exchange,[331,332] and aminocaproic acid to inhibit fibrinolysis.[333] Whether any of these modalities are indicated and, indeed, whether they might be uniformly effective is speculative. If erythrocytapheresis is chosen, the procedure should be done with great care in cyanotic patients. Withdrawal of red blood cells must be accompanied by infusion of an equal volume of fresh-frozen plasma. Simple removal of red blood cells without volume replacement in polycythemic individuals may cause an acute increase in viscosity, vascular collapse, seizures, and even stroke.[334]

Because of the high incidence of cerebrovascular accidents in children with cyanotic congenital heart disease, some have believed that a hypercoagulable state exists. Hyperviscosity alone may account for some ischemic infarctions. The clinician should be alert to the possibility of iron deficiency predisposing patients to stroke in the presence of polycythemia. Several children in whom neurologic deficits developed after the onset of iron deficiency in the presence of polycythemia have been described.[335,336] Card and Weintraub[337] showed that red blood cells from animals with iron deficiency have decreased deformability. Altered deformability in the presence of increased blood viscosity could theoretically result in vascular ischemia.

Platelet Abnormalities

Quantitative and qualitative platelet abnormalities are commonly associated with cardiac disease. Certain syndromes, such as DiGeorge syndrome, Noonan syndrome, and Jacobsen syndrome, are associated with both congenital heart disease and platelet abnormalities.[338] However, even in those without a diagnosed genetic syndrome, platelet abnormalities are commonly found.

In one series, the mean platelet count in cyanotic patients with an arterial oxygen saturation of less than 60% was 185,000 cells/mm^3, as compared with 315,000 cells/mm^3 in patients with an arterial oxygen saturation greater than 60%.[339,340] These abnormalities are readily noted on preoperative evaluation of the coagulation status of individuals about to undergo surgery.[341] Examination of bone marrow has failed to demonstrate any quantitative changes in megakaryocytes to account for these platelet differences.[339] This, together with the finding of shortened platelet survival in many patients, has suggested that the mechanism of the thrombocytopenia is destructive. Shortening of platelet survival with or without thrombocytopenia has been observed in both children and adults with prosthetic heart valves.[342] The increased platelet turnover may result from a combination of mechanical damage to the platelet and adhesion to the foreign material. Some patients, especially those with minimal cyanosis, may have elevated platelet counts. Although iron deficiency is commonly associated with cyanotic congenital heart disease, the quantitative platelet abnormalities are not related to iron status.

Qualitative platelet defects associated with cyanotic congenital heart disease may include abnormal aggregation in response to adenosine diphosphate, epinephrine, and collagen.[343] In as many as 70% of patients, either a delayed or no second wave of platelet aggregation is observed.[344] These platelet functional abnormalities appear to be due to a defective platelet release mechanism because diminished release of carbon-14–labeled serotonin occurs in response to adenosine diphosphate whereas uptake of it is normal.[345] Platelet release abnormalities are more common in patients older than 4 years, in those with a hematocrit greater than 60%, and in those with platelet counts less than 175,000 cells/mm^3.

Miscellaneous Hematologic Manifestations of Heart Disease

Subacute bacterial endocarditis may be associated with a variety of hematologic manifestations. Anemia is often present and is usually the result of chronic infection. The white blood cell count is generally normal, although marked leukocytosis or leukopenia may occur. A 25-year review of the evolving pattern of pediatric endocarditis shows that anemia is present in 40% of children with endocarditis and leukocytosis in 30% of such patients.[346] Pancytopenia has been reported,[347] and thrombocytopenia has been noted in a few patients.[112,113]

Congestive heart failure may result in sufficient hypoxia to cause nucleated red blood cells to appear in the peripheral blood in association with mild reticulocytosis.[114] Thrombocytopenia may be present but is almost exclusively the result of hypersplenism.[348]

Cyanotic heart disease may result in poor perfusion of the spleen and subsequent functional hyposplenism manifested by Howell-Jolly bodies in peripheral blood.[349] This finding is likely to lead to the mistaken conclusion that a child may have the asplenia syndrome (absence of the spleen, cardiovascular malformations, abdominal situs inversus, and other anatomic malformations), which is a separate and distinct diagnosis.

PULMONARY DISEASE

Hypoxia may be caused by a wide variety of pulmonary disorders and, in turn, results in a form of secondary polycythemia and compensatory shifts in the hemoglobin-oxygen dissociation curve that can be attributed to an increase in the red blood cell content of 2,3-diphosphoglycerate (2,3-DPG). Rarely, the polycythemia results in a state of extreme hyperviscosity and decreased tissue blood flow. Other than polycythemia, the hematologic findings of specific pulmonary disorders tend to be unique to those disorders.

Cystic Fibrosis

Patients with cystic fibrosis demonstrate a significant impairment in erythropoietic response to hypoxemia.[350] There is neither an appropriate increase in hemoglobin level nor an adequate shift in the red blood cell–oxygen affinity curve. Failure of the hemoglobin-oxygen dissociation curve to compensate means that such patients may be more symptomatic at any given hemoglobin level than patients who have anemia and other disorders. Disturbances in erythropoietin regulation, as seen in the anemia of chronic disorders and iron deficiency, appear to be the principal cause of the relative anemia in children with cystic fibrosis.[351,352] Deficiencies in vitamin E and iron are also common.[353] If a severe hemolytic anemia is observed in a subject with cystic fibrosis, it may be related to vitamin E deficiency.[354]

Idiopathic Pulmonary Hemosiderosis

Idiopathic pulmonary hemosiderosis (IPH) is an uncommon chronic disease that usually affects children and young adults. However, the age at onset may be as early as the neonatal period.[355] IPH is characterized by recurrent intrapulmonary hemorrhage and may result in hemoptysis and pulmonary insufficiency. The hematologic manifestation of this disorder is iron-deficiency anemia.

The etiology of IPH is not known. A hereditary or familial tendency has been suggested. An immunologic cause seems likely because other occasional findings include positive Coombs test results, the presence of cold agglutinins, and an increased number of mast and plasma cells in the lungs. Autoimmunity is also suggested by frequent association with celiac disease, vasculitis, and collagen vascular disease, as well as by response to treatment with immune suppression. Historically, an association with hypersensitivity to milk has been suggested as well as a structural defect in the alveolar capillaries.[356-358]

The most helpful clinical signs for identifying IPH are iron-deficiency anemia and recurrent or chronic cough, hemoptysis, dyspnea, wheezing, and, frequently, cyanosis. Any single feature may be present without the others. For example, occasionally the only clinical sign is iron-deficiency anemia.[359] Pulmonary symptoms may be present without radiologic findings and vice versa. When pulmonary symptoms are predominant, there may be associated fever, tachycardia, tachypnea, leukocytosis, an elevated sedimentation rate, and, occasionally, abdominal pain.[360] Radiographic abnormalities vary from minimal transient infiltrates to massive parenchymal involvement with atelectasis, emphysema, and hilar adenopathy.[361,362]

The anemia reflects an iron-deficiency state resulting from excessive accumulation of iron in the lungs. This iron is usually sequestered in alveolar macrophages and is largely unavailable for new red blood cell formation. With time, however, the iron is eventually lost from the lungs.[363] In some patients, iron administration fails to correct the anemia. This is usually a reflection of inadequate heme synthesis resulting from the anemia of chronic disease. AIHA may occur. Eosinophilia is found in 15% to 20% of children with IPH.

A diagnosis of IPH may be made by the finding of siderophages in the gastric aspirate. Siderophages will stain positive with Prussian blue dye. Sputum evaluation and bronchoalveolar lavage may reveal hemosiderin-laden alveolar macrophages. If the diagnosis of IPH is seriously being considered, it may be necessary to perform a lung biopsy. Typical findings include alveolar epithelial hyperplasia, degeneration with excessive shedding of cells, large numbers of siderocytes, varying amounts of interstitial fibrosis and mast cell accumulation, elastic fiber degeneration, and sclerotic vascular changes.[364] Electron microscopic examination shows no evidence of subendothelial deposits or basement membrane lesions.[365] No evidence for localization of IgG, IgM, C1q, or fibrinogen has been found.[363] The results of needle aspiration or needle biopsy may also provide a diagnosis.[366]

Treatment of IPH continues to be a controversial subject due to its rarity. In those patients with concomitant celiac disease, a gluten-free diet is recommended. Given the historic link with hypersensitivity to cow's milk, a trial of removal of cow's milk from the diet is appropriate in some instances.[367] Corticosteroid therapy will sometimes produce a remission of disease activity.[368,369] Immunosuppressive therapy may be useful, but the results of such treatment are unpredictable.[370,371]

Pulmonary Hemosiderosis from Other Causes

Clinical findings of hypochromic and microcytic anemia and pulmonary infiltrates may be seen in association with glomerulonephritis (Goodpasture syndrome), collagen vascular disease, Wegener granulomatosis, and, occasionally, SLE.[372-375] Episodes of pulmonary hemosiderosis have also been described in patients with cystic fibrosis and celiac disease.[376,377]

Hematologic Findings in Other Pulmonary Disorders

Sarcoidosis does not usually cause specific hematologic disturbances, although anemia is present in some patients. Sarcoidosis can be associated with splenic enlargement in up to 25% of patients, often with signs of hypersplenism with anemia, leukopenia, and thrombocytopenia. A higher than average incidence of blood group antigen A has been reported in this disorder.[378,379] Bone marrow granulomas are noted occasionally.[380] The significance of this finding is not known, but the altered immune response of these patients[381] and an association of sarcoidosis with hemolytic anemia[382] and immune thrombocytopenia[383-386] suggest that sarcoidosis represents a generalized autoimmune disorder.

Eosinophilia may be observed in a variety of pulmonary disorders, including asthma, Löffler syndrome, tropical pulmonary eosinophilia, polyarteritis nodosa, and sarcoidosis.

RENAL DISEASE

Renal disease may produce disturbances in red blood cells, white blood cells, platelets, and coagulation factors. In many instances, the abnormalities that are found do not parallel the status of renal function but rather reflect the activity of the disease process that results in renal dysfunction. The hematologic aspects of renal insufficiency have been reviewed in detail.[387]

The Red Blood Cell

Anemia

Anemia is a common finding in acute and chronic renal disease and is often so severe in these conditions that it constitutes the major morbidity of renal disease.[388] Although the anemia is often multifactorial, the main cause is erythropoietin deficiency.[389] Progressive renal disease is accompanied by an erythropoietin decline that results in a hypoproliferative, usually normochromic, normocytic anemia. However, other factors can intervene to impair erythropoietin responsiveness and aggravate already low levels of the hormone. These include infection and inflammation (anemia of chronic disease), inadequate dialysis, and secondary hyperparathyroidism.[390,391] In patients treated with erythropoietin, deficiencies of cobalamin (vitamin B_{12}), folic acid and, especially, iron may limit response. Transfusion support frequently becomes a necessary intervention, although elevated 2,3-DPG levels and a right-shifted oxygen dissociation curve make the red blood cells of uremic subjects more effective in the delivery of oxygen than normal red blood cells.[392] The anemia usually develops when the creatinine clearance decreases below 35 to 45 mL/min, although no direct correlation is found between the severity of the anemia and the degree of renal impairment. The hemoglobin level is generally in the 7- to 8-g/dL range in uremic states.

Decreased red blood cell production is the major cause of the anemia of chronic renal failure. Although deficiency in erythropoietin production is the primary cause of decreased red blood cell production in renal failure,[393,394] suppression of hematopoiesis by serum inhibitors may be a contributing factor.[395,396] In patients with acute or chronic renal failure as a result of nephrectomy, normal or even increased erythropoietin production can be maintained.[397] Several series have documented improved hematocrits and erythrocyte volumes proportional to the intensity of dialysis treatments, which may remove the inhibitors.

In addition, excess parathyroid hormone is also an inhibitor of erythropoiesis in uremia, a defect that renal failure states share with primary hyperparathyroidism.[398] The mechanism of this contribution to anemia[399] is likely due to the replacement of the marrow cavity by fibrous tissue in hyperparathyroid states. Removal of hypertrophied parathyroid glands improves the osteitis fibrosa of involved marrows and the anemia that accompanies this abnormality.[400,401] Treatment with 1,25-dihydroxycalciferol also decreases marrow fibrosis and diminishes the anemia of renal failure.[402,403] The role of parathyroid hormone in these anemias is in remodeling the environment in which hematopoiesis takes place; the more advanced states of bone disease seen in patients with uremia may even lead to splenomegaly secondary to extramedullary hematopoiesis.[404]

In renal disease, unlike many other chronic disease states, close correlation exists between erythrocyte mass and erythrocyte survival.[405] This implies that shortening of red blood cell survival has an important role in the development of anemia in these patients. About 70% of patients with renal disease have shortened red blood cell survival related to a host of potential alterations. These cells demonstrate increased mechanical fragility, autohemolysis, diminished deformability, and a variety of metabolic defects.[406,407]

A circulating inhibitor of red blood cell metabolism accumulates in some but not all uremic patients. This inhibitor diminishes recycling of glucose through the hexose monophosphate shunt,[406] a defect that may be clinically important. There are several reports of severe hemolytic disease in uremic patients given sulfa drugs. Because of this problem, caution in the use of oxidant drugs is advised in those with azotemia.[408] The decreased shunt activity may be secondary to a metabolic defect within the shunt itself or due to a block within the main glycolytic pathway. Other incidental causes of hemolysis may be observed during hemodialysis. Contaminants such as copper, nitrate, and chloramines in hemodialysis baths may cause varying degrees of hemolysis.[409-411]

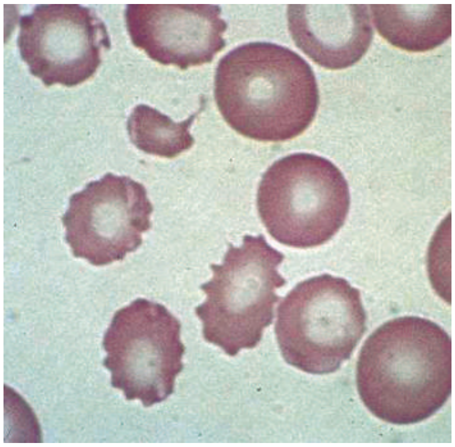

Figure 37-13 Burr cells caused by uremia.

The erythrocytes of patients with renal disease are generally normochromic and normocytic without any distinguishing morphologic characteristics. Occasionally, scalloped or burr cells are observed, usually in association with uremia secondary to specific causes or related to specific syndrome complexes such as hemolytic uremic syndrome (Fig. 37-13).[412] In diseases associated with microangiopathic hemolytic anemia, red blood cell fragmentation is common. It may be observed in patients with malignant hypertension, renal cortical necrosis, polyarteritis nodosa, hemolytic uremic syndrome, SLE, and TTP.

Anemia associated with megaloblastic changes in bone marrow is not uncommon in chronic renal failure. This anemia is usually due to folate deficiency[413] caused by poor dietary intake, hemodialysis, peritoneal dialysis, or the effects of immunosuppressive drugs. In addition, defective protein-mediated folate transport may be present.[414] Serum from uremic patients may contain an increased concentration of folic acid–binding protein.[414] Folate deficiency is usually suspected when large numbers of macroovalocytes are seen in association with hypersegmentation of polymorphonuclear leukocytes on the peripheral blood smear. The anemia of renal disease can also be worsened in dialyzed patients by superimposition of iron deficiency due to blood loss during hemodialysis.

The primary role of erythropoietin deficiency in the anemia of renal failure has been incontrovertibly confirmed with the successful trials of recombinant human erythropoietin in both dialyzed and nondialyzed renal failure patients (see Chapter 1).[415,416] Administration of the hormone has eliminated the need for red blood cell transfusions or androgens, previously the mainstays in treating the anemia of renal failure.[417,418] The therapeutic success of erythropoietin-stimulating agents (ESAs) has brought to a close any doubts concerning the major cause of the anemia of renal failure.[419,420] The administration of ESAs may unmask iron and folate deficiency, their presence being signaled by an apparent refractoriness to erythropoietin administration.[421] Controversy exists about the goal hemoglobin level in patients with renal insufficiency treated with ESAs, although most data support a lower hemoglobin level of 10 to 11 g/dL.[422,423] Administering ESAs to reach higher target hemoglobin levels greater than 13 g/dL is associated with fewer red blood cell transfusions; however, higher hemoglobin levels are also associated with an increased risk for stroke, hypertension, and thrombosis.[424,425] It remains unclear whether the higher hemoglobin is linked to these adverse outcomes or high doses of ESAs.

Polycythemia

Secondary erythrocytosis is a well-recognized complication of renal disorders. The increase in red blood cell mass is due to release of erythropoietin directly from renal tumor cells, renal ischemia, and hydronephrosis and in association with chronic glomerulonephritis, pyelonephritis, nephrosclerosis, and nephrotic syndrome in adults.[426,427] Erythrocytosis is also a common finding after renal transplantation.[428]

The White Blood Cell

Azotemia and uremia per se appear to have relatively little effect on white blood cell function. Granulocytopenia is common during hemodialysis[429] and appears to be due to transient sequestration of granulocytes in the pulmonary vascular bed followed by later release back into the circulation. After hemodialysis, a transient augmentation in granulocyte adherence coincides with the time of sequestration of the pulmonary vascular bed.[430] The adherence-augmenting factor in the plasma of patients undergoing dialysis is heat stable.

Neutropenia as a result of folate deficiency may be present in patients with renal failure. The cause of the neutrophil nuclear hypersegmentation associated with uremia is unknown and should not necessarily be attributed to folate deficiency.

Vascular occlusion of the kidney may result in eosinophilia. Approximately 80% of adult subjects with embolic renal disease have eosinophil counts ranging from 540 to 2000 cells/mm^3.[431]

Coagulation Abnormalities

Patients with uremia may have varied changes in some coagulation factors. Among the most common abnormalities observed are mild to moderate depressions in factors V, VII, IX, and X.[432,433] These abnormalities are related to the high incidence of hepatic dysfunction in patients with uremia or vitamin K deficiency.[343] The level of fibrinogen is regularly elevated because it is an acute phase reactant.[434-436] Increased fibrinogen turnover has been demonstrated in experimental models,[437] and excessive fibrin degradation products have been found in the urine and serum of uremic patients.[438] When a decrease in one or more consumable clotting factors (factors I, II, V, or VIII) is also present, it may signify the existence of consumptive coagulopathy.[432,433,439] Because fibrin deposition may occur in the absence of such a coagulopathy, it is often helpful to determine whether high-molecular-weight fibrin degradation products are present in the urine and serum. If found only in the urine, such products are probably derived from the dissolution of fibrin deposits in the kidneys. If demonstrable simultaneously in urine and serum, their presence indicates renal injury because such degradation products cannot be demonstrated in the urine of patients with streptokinase-induced fibrinolysis who have no renal disease.[440,441] Fibrin degradation products in the urine and serum usually indicate active renal disease, although other reasons for this finding may be seen in patients with renal disease. Fibrin degradation products may also result from concomitant liver disease or from an external shunt used for hemodialysis.[337] Urinary fibrinolytic activity is either diminished or absent in renal failure, and inhibitors of urokinase-induced plasminogen activation are demonstrable.[440]

Nephrotic syndrome is often accompanied by changes in a number of coagulation factors.[442] Increased levels of fibrinogen, factor VIII, and the factor VII-X complex are commonly present.[443] A prolonged partial thromboplastin time is often observed and is usually due to a decrease in the plasma level of factor IX.[444] Factor IX is consistently found in urine containing more than 10 g of protein per 24 hours in patients with nephrotic syndrome.[445] Plasma levels of factor IX rarely decrease to less than 10%, and clinical bleeding episodes are unusual. With resolution of the proteinuria in patients receiving corticosteroid therapy, levels of factor IX increase. Factors II and VII have also been identified in considerable quantity in the urine of patients with nephrotic syndrome despite normal levels of these factors in plasma.[446] This finding suggests that loss of some coagulation factors into urine can be fully compensated for by an increased rate of synthesis. A prolonged partial thromboplastin time may also be due to a low level of Hageman factor (factor XII).[447] Hageman factor has a molecular mass of approximately 75,000 kD, similar to that of albumin, and losses in urine are to be expected.[448] Although factor XII levels may decrease to less than 10%, as with congenital deficiency of this factor, bleeding is not encountered. Patients with nephrotic syndrome appear to have a substantially higher risk for thromboembolic complications.[440] The coagulation defects associated with nephrotic syndrome have been reviewed by Kaufmann and colleagues.[449]

The hypercoagulable state seen in many forms of renal disease may be compounded by the occurrence of lupus-like anticoagulants. This is common in a variety of end-stage renal diseases, with a rate of occurrence as high as 22%.[450] Whether therapy focused on prevention of fibrin deposition within the kidney is of benefit to patients with certain forms of glomerulonephritis remains uncertain. Kincaid-Smith[451,452] used a combination of an anticoagulant, dipyridamole, and cyclophosphamide in a series of patients with membranoproliferative glomerulonephritis. A similar approach was reported by Robson and associates,[453] but with azathioprine substituted for cyclophosphamide. In both studies, it was suggested that these therapies produced improvement in the patients' clinical course. The concept of anticoagulation therapy for these disorders has been reviewed.[454]

Platelet Abnormalities

Mild thrombocytopenia occurs in approximately 25% of patients with acute renal failure and 10% of those with chronic renal disease.[455] The thrombocytopenia is most likely due to impaired production, because platelet life span in uremia is generally normal.[435]

Platelet function is abnormal in patients with renal failure. The standardized Ivy bleeding time is usually prolonged and generally correlates with the clinical tendency for bleeding in these patients.[456] Platelet adhesion and platelet factor 3 availability are diminished in acute and chronic uremia.[457] Impaired aggregation of platelet-rich plasma in the presence of adenosine diphosphate,[458] epinephrine,[459] thrombin,[459] and collagen[459] has been observed. Clinical bleeding episodes related to these platelet abnormalities can usually be managed with desmopressin given intravenously.[460] Long-term administration of recombinant erythropoietin also improves the biochemical and functional changes in the platelets of uremic patients.[461] Rarely, enhanced platelet function characterized by hyperaggregability has also been observed in uremia.[462]

Platelet functional abnormalities are not due to an intrinsic platelet defect because dialysis quickly reverses these changes and incubation of normal platelets in plasma from uremic patients promptly induces functional aberrations. Rather, platelet dysfunction appears to be due to the interaction of intrinsically normal platelets with various abnormal dialyzable metabolites found in the plasma of uremic patients.[463] If urea and creatinine levels are elevated, some of these findings can be reproduced.[463] Phenols[434] and guanidinosuccinic acid,[464] which accumulate in the plasma of uremic patients, can also account for platelet functional abnormalities. These findings are discussed in detail in Chapter 34.

Several hereditary disorders have been reported in which quantitative or qualitative platelet abnormalities occur in association with nephritis. MYH9 disorders are caused by defects in the myosin heavy chain IIa and associated with macrothrombocytopenia and a bleeding tendency. Because myosin IIA is a major component of the podocyte foot process and maintains capillary wall integrity, many MYH9 disorders, including Epstein syndrome, Fechtner syndrome, and Sebastian platelet syndrome, are associated with kidney dysfunction in addition to hearing loss and cataracts.[465,466] In these disorders it is hypothesized that disordered early platelet release contributes to the thrombocytopenia. The inherited platelet disorders are discussed in Chapter 30.

The pathophysiology and management of hemolytic uremic syndrome are discussed in Chapter 34.

GASTROINTESTINAL DISEASE

Hematologic complications of gastrointestinal disease appear in many disorders. This section does not include the wide range of situations in which blood loss from the gastrointestinal tract occurs but rather focuses on specific diseases and their hematologic complications.

Diseases of the Gastrointestinal Tract

Esophagus

Plummer-Vinson syndrome (dysphagia, postcricoid webs, and iron deficiency)[467] occurs in older individuals and is discussed in Chapter 11. Iron-deficiency anemia may be the only manifestation of gastroesophageal reflux; thus endoscopy is important in the evaluation of unexplained iron-deficiency anemia.[468] Chronic gastroesophageal reflux may cause Barrett esophagus with its attendant risk for the development of adenocarcinoma.[469]

Stomach

The gastric mucosa is important in both vitamin B_{12} and iron absorption, and disorders of the gastric mucosa may cause defective absorption of either of these nutrients. The gastrointestinal causes of iron and vitamin B_{12} deficiency are reviewed in Chapters 10 and 11.

Gastric resection may result in iron or vitamin B_{12} deficiency, the former from bleeding at sites of anastomosis and the latter, years later, from lack of intrinsic factor. Vitamin B_{12} deficiency may develop in infants breastfed by women who have undergone gastric or intestinal bypass procedures.[470] Macrocytic, megaloblastic anemia resulting from vitamin B_{12} deficiency has been reported in association with gastric trichobezoars.[471] This is presumed to be due to bacterial overgrowth of the upper gastrointestinal tract. In congenital intrinsic factor deficiency, gastric biopsy results are normal and no antibodies to parietal cells or intrinsic factor are present.[472]

Small Intestine

Celiac disease and inflammatory bowel disease are both frequently associated with anemia and are covered in detail in Chapter 11.

Crohn disease has also been associated with coagulopathy, particularly with acute flares. Low factor XIII levels have been observed in active disease associated with regional enteritis.[473] An abnormality in arachidonic acid metabolism may occur in patients with chronic inflammatory bowel disease, including regional enteritis. This may result in alterations in platelet function.[474] Diminished neutrophil function may be seen in both regional enteritis and other forms of inflammatory bowel disease. The condition may be identified by decreased oxidative metabolism and low superoxide dismutase content of neutrophils.[475] Perinuclear antineutrophil cytoplasmic antibodies are commonly found in patients with inflammatory bowel disease.[476,477] Inflammatory bowel disease, particularly during acute flares, is also associated with an increased risk for thrombosis.

Disorders such as tropical sprue, celiac disease, bowel lymphoma, amyloidosis, and connective tissue disturbances (including Ehlers-Danlos syndrome and pseudoxanthoma elasticum) may produce panselective or selective malabsorption. Certain disorders such as intestinal lymphangiectasia may cause protein loss of a magnitude sufficient to impair globin chain synthesis. Protein loss may also be associated with selective loss of T lymphocytes into the bowel lumen, which causes lymphopenia and altered delayed-type hypersensitivity. This lymphopenia may be associated with hypogammaglobulinemia.[478]

Eosinophilic gastroenteritis is a disorder most often characterized by recurrent bouts of abdominal pain, nausea, vomiting, diarrhea, and an elevated peripheral blood eosinophil count for which there is no other explanation.[479] The gut wall may be infiltrated by eosinophils.[479]

Common diarrheal illnesses during infancy may result in life-threatening methemoglobinemia, especially if the diet has been high in nitrates.[480-483]

Large Intestine

Ulcerative colitis is often associated with iron-deficiency anemia as a result of blood loss. AIHA identified by positive results of a Coombs test and immune thrombocytopenia are relatively rare complications of ulcerative colitis, however, and develop in less than 1% of patients.[484] Occasionally, vitamin B_{12} deficiency occurs after many years if a "backwash" ileitis is present. Polymorphonuclear leukocytosis is common. Occasionally, an increase in plasma fibrinolytic activity will be observed. A significant decrease in antithrombin III levels may be found.[485] Some clinicians have treated this complication with ε-aminocaproic acid.[486] Platelet functional abnormalities may exist and are discussed in Chapter 34. Alterations in T-cell subsets may also occur in children with inflammatory bowel disease.[487]

Constipation has been reported to cause an increase in sulfmethemoglobin levels.[488] It has been suggested that excess nitrite absorption from the gut may be present in some patients as a result of abnormal bowel function.[489]

Symptoms of Peutz-Jeghers syndrome (gastrointestinal polyposis and mucocutaneous pigmentation) may occur in early childhood and are associated with an increased risk for intestinal cancer.[490,491]

Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease) may result in iron deficiency from gastrointestinal bleeding. Alterations in hemostasis (DIC, platelet dysfunction, and factor XI deficiency) have been reported.[492] An association between this disorder and von Willebrand disease may exist.[493]

Disease of the Pancreas

Acute hemorrhagic pancreatitis may cause acute anemia during the first week of the illness as a result of hemodilution, intravascular coagulation, and blood loss.[494] Leukocytosis with neutrophilia is a usual finding. Markedly elevated levels of fibrin split products usually suggest that a consumptive coagulopathy is present. A concomitant decrease in platelet count is also common.[495] High levels of methemalbumin are common in the ascitic fluid of individuals with hemorrhagic pancreatitis[496] and can be used to distinguish this disorder from nonhemorrhagic pancreatitis. Patients with ascitic fluid are the ones most likely to have evidence of consumptive coagulopathy. For example, fibrin degradation products are seen in 40% of subjects with fulminant pancreatitis without ascites but in 100% of patients with clinically apparent peritoneal fluid.[497]

Shwachman-Diamond syndrome and Pearson syndrome with associated congenital exocrine pancreatic insufficiency and bone marrow failure are discussed in Chapter 7.

Cystic fibrosis may cause malabsorption, which produces the expected hematologic abnormalities. A specific pattern of anemia in association with edema and hypoproteinemia may be observed in some children with cystic fibrosis. It is found most commonly in children who have low dietary intake of nitrogen, such as those who receive their protein primarily from breastmilk or soybean formula.[498] The edema is caused by hypoalbuminemia. The anemia responds to adequate dietary protein enrichment and pancreatic enzyme supplementation but not to iron administration. Cystic fibrosis may also be associated with malabsorption of fat-soluble vitamins, and the consequent coagulopathy is related to vitamin K deficiency. Vitamin E deficiency may also occur and is manifested by mild hemolytic anemia and abnormal red blood cell peroxide hemolysis, as well as by hyperaggregation of platelets.[499]

Diseases of the Liver

Red Blood Cell Disturbances

Anemia is common in acute and chronic liver disease and has a diverse etiology.[500] Liver disease is often accompanied by increased portal pressures, with the resultant congestive splenomegaly potentially creating any combination of anemia, leukopenia, or thrombocytopenia. The marrow's compensation for such hemolytic insults is frequently dampened or absent in the setting of liver disease because of concomitant vitamin nutritional deficiencies. In addition, portal hypertension and liver disease are associated with increased risk for bleeding and concomitant iron deficiency. Shortened red blood cell survival may be observed in some patients with no evidence of blood loss.[501,502] The exact mechanism by which red blood cell survival is shortened is unclear.

Erythrocytes from patients with active liver disease have an increased tendency to form Heinz bodies after incubation with an oxidant chemical such as acetylphenylhydrazine or sodium ascorbate. This increase in Heinz body formation is associated with increased instability of red blood cell reduced glutathione, decreased hexose monophosphate shunt activity, and reduced glucose recycling through the hexose monophosphate shunt.[503] Activation of superoxide dismutase and glutathione reductase may be observed in the red blood cells of patients with profound liver disease. This may partially explain the alterations in the antioxidant system noted with these disorders.[504] The hemolytic anemia associated with liver disease secondary to Wilson disease is especially severe.[505] The same is true of the hemolytic anemia related to protoporphyria.[506]

The exact significance of these metabolic alterations has not yet been determined. Red blood cell metabolism appears to return to normal within a few weeks after an insult to the liver. All of the metabolic consequences of liver disease can be reproduced in normal intact red blood cells by prolonged incubation in plasma from patients with active liver disease. In patients with active liver disease, it may be wise to withhold any drug that has the potential to present an oxidant challenge to the red blood cell. Similar acquired abnormalities in hexose monophosphate shunt activity have been associated with drug-induced hemolysis in patients with uremia.[507]

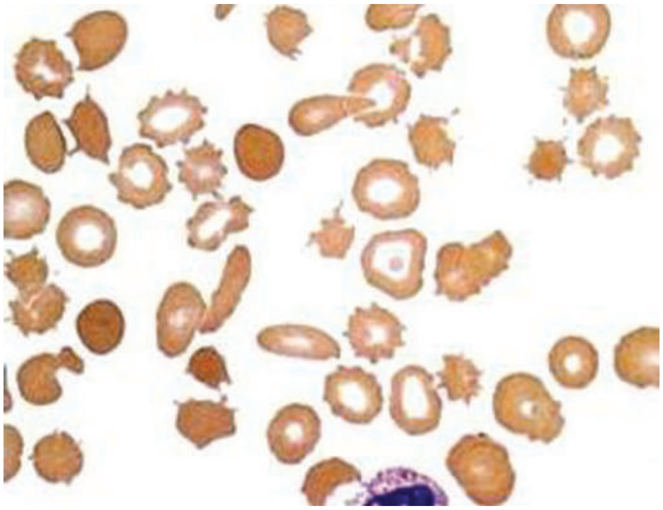

Figure 37-14 Acanthocytes and target cells due to liver disease.

The red blood cells in liver disease are often macrocytic, with mean corpuscular volumes in the range of 100 to 110 fL. In patients with biliary obstruction, the red blood cell surface lipids increase and cause target cells. With severe hepatocellular damage, acanthocytes or spur cells are commonly observed (Fig. 37-14).[508,509] These morphologic abnormalities appear to be in direct proportion to the increase in red blood cell membrane cholesterol that accompanies hepatocellular liver disease.[510-512] Increased osmotic resistance is a consequence of the increased red blood cell surface area. Stomatocytosis has been reported in alcoholic liver disease.[513]

Coagulation Abnormalities

Because the liver is involved to some extent in the synthesis of most of the coagulation factors, it is not unexpected that liver dysfunction would be associated with the presence of abnormal clotting studies and bleeding. The coagulation abnormalities common in patients with fulminant hepatic failure have been reviewed in detail.[514,515]

Patients with liver disease commonly manifest a spectrum of coagulation abnormalities that are highly suggestive of DIC.[516,517] Findings consistent with DIC include hypofibrinogenemia, thrombocytopenia, increased fibrinogen catabolism, increased levels of fibrin degradation products, and depressed levels of other coagulation factors. This pattern of abnormalities is not specific for DIC and may simply reflect the severity of the hepatocellular disease process. For example, fibrinogen levels may be depressed on a synthetic basis alone. Increased catabolism of fibrinogen may reflect distribution in extravascular spaces, such as the formation of ascitic fluid or proteolysis by enzymes other than thrombin. Thrombocytopenia may occur for a variety of reasons and frequently is not present when other signs of DIC are seen. Changes in levels of factors V and VIII are varied and nonspecific. Because fibrin degradation products are cleared by the liver, severe liver dysfunction itself may cause elevations of these products without implicating DIC.[515]

TABLE 37-4 Hematologic Effects of Thyroid Hormone

↑ Thyroid Hormone	↓ Thyroid Hormone
↑ PRBC volume	↓ PRBC volume
Variable effect on RBCs	↑ Or normal MCV; spiculated RBCs
↑ Glucose utilization and hexose monophosphate shunt activity	↑ O_2 affinity
↓ RBC glutathione, reduced	↓ 2,3-Diphosphoglycerate
↑ Red blood cell 2,3-diphosphoglycerate	↓ RBC Na^{+}
↓ O_2 affinity	↓ Platelet adhesion
↑ Diphosphoglycerate mutase activity	↓ (Slight) platelet aggregability
↑ Glyceraldehyde-3-phosphate dehydrogenase	↓ Factor VIII activity
↑ Glucose 6-phosphate activity	↑ Fibrinolytic activity
↓ RBC carbonic anhydrase	↑ Plasminogen
↓ RBC zinc	↑ Plasminogen activation
↑ RBC Na^{2+}	
↑ (Slight) platelet turnover	↓ Capillary fragility
↑ Platelet adhesion	↑ Factors VIII, VII, IX, XI activity
↑ Platelet aggregability	
↑ Factor VIII activity	
↓ Plasminogen activation	
↑ Capillary fragility	

MCV, Mean corpuscular volume; *PRBC,* packed red blood cell; *RBC,* red blood cell.

The acquired coagulation abnormalities of liver disease are discussed in detail in Chapter 35.

ENDOCRINE DISORDERS

Disturbances in endocrine balance tend to produce relatively mild hematologic abnormalities. The most thoroughly evaluated of these abnormalities are those caused by thyroid disorders.

Thyroid Gland

Thyroid hormone appears to have many hematologic effects (Table 37-4), with the most impressive being its effect on erythropoiesis. Individuals with hyperthyroidism sometimes have an elevated red blood cell mass secondary to the effects of excessive thyroid hormone and have an increased requirement for folic acid to accommodate the increased red blood cell synthesis.[518] The red blood cells of patients with hyperthyroidism may have increased osmotic resistance.[519] The red blood cell sodium concentration is significantly increased in hyperthyroidism, and decreased sodium pump activity may be present.[520] A macrocytic anemia may complicate hyperthyroidism in the setting of Graves disease because pernicious anemia and other immune disorders are linked to Graves disease.[521,522] Neutropenia may occur in approximately 5% of children with hyperthyroidism.[523] The mechanism of this abnormality is unclear, although some patients will have antineutrophil antibodies.[524]

The anemia of hypothyroidism is caused by a reduced red blood cell mass secondary to the decreased oxygen requirements of the hypothyroid state.[525,526] The anemia is usually normochromic and normocytic and occasionally mildly macrocytic.[527] Patients with hypothyroidism often (20% to 65%) have a small number (0.5% to 2%) of acanthocytes on peripheral blood smears.[528] Given the high incidence of hypothyroidism relative to other disorders that cause acanthocytosis, it has been suggested that the presence of acanthocytes should prompt physicians to consider thyroid testing, especially in adults. This approach has led to the diagnosis of previously unsuspected hypothyroidism. Red blood cell survival is normal, and ferrokinetic studies demonstrate a decreased rate of iron clearance. In adults with hypothyroidism, an unusually high incidence of iron deficiency, often linked to menorrhagia, and pernicious anemia is found.[529,530]

Thyroid hormone may play a role in the regulation of red blood cell metabolism. Thyroxine has been reported to increase red blood cell glycolysis.[531] It helps regulate red blood cell carbonic anhydrase I concentrations.[532] Hexose monophosphate shunt activity may increase in the presence of triiodothyronine.[533] The activity of glucose-6-phosphate dehydrogenase is consistently elevated in thyrotoxicosis, whereas normal levels are found in most patients with mild hyperthyroidism.[534] Glutathione levels are usually depressed in hyperthyroidism. Thyroid hormone may affect the activities of several other red blood cell enzymes. This hormone stimulates diphosphoglycerate mutase and glyceraldehyde-3-phosphate dehydrogenase.[535] These effects may be the cause of the elevated levels of red blood cell 2,3-DPG that are seen in patients with hyperthyroidism and that result in decreased whole blood oxygen affinity and a shift to the right in the hemoglobin-oxygen dissociation curve.[536] Opposite effects are seen in hypothyroidism. The carbonic anhydrase activity of erythrocytes is diminished in hyperthyroidism and increased in hypothyroidism. Because red blood cell zinc is almost exclusively contained in carbonic anhydrase, hyperthyroidism will result in a decrease in total red blood cell zinc levels.[537]

Multiple effects on platelets and blood coagulation factors may occur in thyroid disease states. Marked hyperthyroidism may reduce platelet survival.[538] Egeberg[539] reported on a patient with hypothyroidism who had a prolonged bleeding time and low factor VIII activity, similar to findings in von Willebrand disease.

Simone and associates[540] reported on patients with hypothyroidism who had multiple coagulation factor deficiencies. Diminished platelet responsiveness to epinephrine and low platelet adhesiveness may be present as well.[541] Impressively low levels of factor VIII occur occasionally, with milder depression of factors VII, IX, and XI being found either alone or in combination.[542] In hypothyroidism, increased plasma fibrinolytic activity may result from an elevation in plasma plasminogen and a decrease in an inhibitor of plasminogen activation.[542,543] This may account for the mild to moderate increase in levels of fibrinogen and fibrin split products occasionally found in patients with hypothyroidism.[542]

Hypothyroidism is also associated with acquired type I von Willebrand disease in 2% to 5% of cases.[544] The low von Willebrand factor antigen is due to a reduction in its synthesis and/or secretion.[544] Similar to inherited type I von Willebrand disease, acquired von Willebrand disease in hypothyroidism is associated with mucocutaneous bleeding and responds to desmopressin and antifibrinolytic agents.[545,546] Acquired von Willebrand disease typically reverses with correction to a euthyroid state.

Adrenal Gland

Adrenal corticosteroids appear to have a stimulatory effect on erythropoiesis. In Addison disease, the adrenal insufficiency may cause mild to moderate anemia, probably as a result of reduced basal metabolism. In most patients, a decrease in plasma volume masks the decreased red blood cell mass. After treatment of adrenal insufficiency, the plasma volume corrects quickly, whereas the red blood cell mass responds over a period of several weeks. The usual effect of treatment is therefore a prompt decrease in hemoglobin concentration followed by a gradual increase.[547] In addition to anemia in Addison disease, neutropenia, eosinophilia, and lymphocytosis are common.[548]

Erythrocytosis may occur in Cushing syndrome, but in most patients the reported increase has been slight. Cushing syndrome is also associated with coagulation abnormalities, suggesting a hypercoagulable state.[549]

A variety of effects on leukocytes occur after corticosteroid administration or endogenous overproduction of a corticosteroid, including granulocytosis, a reduced lymphocyte count, involution of lymphatic tissue, and a decrease in peripheral blood eosinophils and monocytes. The mechanism by which endogenous or exogenous corticosteroids lower the number of circulating eosinophils is unknown.

Pituitary Gland

The hematologic effects of pituitary disease are usually a consequence of the action of trophic hormone on target endocrine organ function. For example, anemia is common in patients with hypopituitarism.[550] This normochromic, normocytic anemia is associated with findings of lymphocytosis and eosinophilia, which indicate that this effect of hypopituitarism results from adrenal insufficiency. Erythropoietin production may be diminished as a consequence of a lower metabolic rate.

Growth hormone may play an important role in erythropoiesis.[551] This hormone stimulates erythropoiesis directly and indirectly by increased production of erythropoietin. The red blood cell count may decrease with isolated growth hormone deficiency.[552] Erythrocyte glucose-6-phosphate dehydrogenase activity is low in hypopituitarism and increases with growth hormone administration.[553] Growth hormone depresses erythrocyte glycolysis.[554]

Other Endocrine Disorders

Hematologic abnormalities are rare in association with gonadal dysfunction. Androgens stimulate erythropoiesis, whereas estrogens, in general, depress red blood cell production. Castration of the adult male results in a definite decrease in red blood cell mass.[555] In disorders associated with androgen excess, such as Cushing syndrome and congenital adrenal hyperplasia, the hemoglobin concentration may exceed normal values. Exogenous androgen administration may cause polycythemia and may also increase red blood cell 2,3-DPG.[556] Androgens appear to stimulate erythropoiesis by increasing erythropoietin production, as well as by having a direct effect on bone marrow stem cells.

Diabetes Mellitus

It has long been recognized that diabetic patients are prone to anemia,[557] infection,[558] and thrombotic episodes with macrovascular and microvascular sequelae.[559]

Red Blood Cells

An unusual hemoglobin component in hemolysates prepared from the blood of some diabetic patients was first noted by Rahbar.[560] A component that migrated near the position of fetal hemoglobin was described on agar gel electrophoresis at pH 6.2 in citrate buffers. This hemoglobin is present in normal individuals; it constitutes 5% to 7% of total hemoglobin[561] and is called hemoglobin A_{1c}. Rahbar's group observed a twofold increase in this hemoglobin fraction in some diabetic patients.[562] Structurally, hemoglobin A_{1c} is a condensation product, by means of a Schiff base, between one molecule of hemoglobin A and one molecule of an aldehyde or ketone, linked at the amino-terminals. The aldehyde or ketone group appears to be one or more hexoses, thus making hemoglobin A_{1c} a glycohemoglobin. Bunn and Briehl[563] have shown that the oxygen affinity of hemoglobin A_{1c} is little affected by the addition of 2,3-DPG, which leads to decreased oxygen affinity when added to hemoglobin A. Studies have shown highly significant relationships between the percentage of hemoglobin A_{1c} and the response to an oral glucose tolerance test and overall diabetic control, as reflected in quantitative urinary glucose determinations.[564,565] In this sense, measurement of the glycohemoglobin provides an insight into diabetic control over many days.

Red blood cell survival, as measured by chromium (^{51}Cr) labeling, may be mildly impaired during periods of poor diabetic control (mean erythrocyte half-life of 27 days). With improvement of diabetic control, red blood cell survival will increase (mean half-life of 31 days).[566] During episodes of ketoacidosis, rapid shifts in the oxygen affinity of hemoglobin may also occur. A decrease in pH causes a shift to the right with an increase in oxygen unloading. Very rapid correction of pH may impede oxygen delivery. A prompt decrease in red blood cell 2,3-DPG levels occurs at these times.[567] This decrease is probably compensatory—an attempt to correct the oxygen affinity disturbances caused by the acidosis. A decrease in red blood cell 2,3-DPG levels may also result from hypophosphatemia, if it occurs during insulin treatment.

Other red blood cell abnormalities have been found in diabetic subjects. The red blood cells of such individuals show evidence of lipid peroxidation and antiperoxidative enzyme changes when compared with those of healthy subjects.[568] An increase in the glycosylated form of erythrocyte superoxide dismutase has been found in diabetic subjects and is related to nonenzymatic glycosylation of this enzyme.[569] Erythrocytes from diabetic subjects also show sodium influx.[570] Red blood cell sorbitol concentrations will increase in subjects with poorly controlled diabetes; the amount of red blood cell sorbitol is related to the degree of diabetic control.[571] Finally, if electronic counting equipment is used to determine the mean corpuscular volume of red blood cells, artifactual elevations in mean corpuscular volume may be seen in subjects with hyperglycemia.[572]

Thiamine-responsive megaloblastic anemia, diabetes mellitus, and sensorineural deafness is a rare autosomal recessive disorder[573,574] that begins in childhood and is caused by defects in the high-affinity thiamine transporter-1 *(SLC19A2)*, on chromosome 1q23.3.[575-577] The anemia and diabetes respond to high-dose thiamine treatment, although the diabetes can relapse years later, despite continued thiamine treatment.[578]

White Blood Cells

Polymorphonuclear cell function may be disturbed in diabetic patients. Leukocyte adherence is diminished in individuals with poor control of diabetes, as is phagocytic capacity.[579] Chemotaxis may also be abnormal, but this does not correlate with the status of diabetic control.[580] Impaired cellular metabolism and DNA synthesis have been reported in the lymphocytes of some patients with diabetes.[581] Increased superoxide production by mononuclear cells is observed in patients with diabetes and hypertriglyceridemia.[582]

Platelets

Many studies have emphasized the abnormalities in platelet adhesion and aggregation in patients with diabetes. The finding that enhanced platelet aggregation occurs before clinical evidence of diabetic vascular disease suggested that this defect may be acquired early in the natural history of diabetes and could underlie the vascular disease.[583] Platelet aggregation in diabetic subjects is characterized by a shortened adenosine diphosphate–induced aggregation time.[584] Increased platelet adhesiveness and platelet factor 3 and 4 activity also occur.[566,585] Normal platelets incubated in the plasma of diabetic patients will become abnormal. This aggregation-enhancing activity is present in both plasma and serum and is nondialyzable and heat resistant.[584] In patients with this plasma factor, von Willebrand factor activity is also increased, thus suggesting that the two are related.[586] The enhanced in vitro responsiveness of platelets from diabetic patients can be decreased by prostaglandin synthetase inhibitors.[583,587] Platelets from diabetic patients demonstrate increased activity of the prostaglandin synthetase system, which results in increased synthesis of prostaglandin endoperoxides and, therefore, of prostaglandin E_2.[588] When induced to aggregate with arachidonic acid, the platelets of diabetic patients with vascular disease tend to produce more thromboxane A_2 than those of normal subjects do.[589] A lower prevalence and severity of diabetic retinopathy have been observed in a group of diabetic patients with concurrent rheumatoid arthritis who were taking high doses of aspirin. This finding suggests that inhibition of platelet aggregation and prostaglandin synthesis may be desirable in the management of diabetic patients.[590] The increased glycosylation of connective tissue proteins in diabetic patients has been suggested to increase their aggregation potency.[591]

Other Hematologic Findings in Diabetes Mellitus

A state of hypercoagulability associated with changes in clotting factors and platelet function has been postulated to be important in the increased thrombotic complications in diabetic patients. Approximately a third of patients with diabetes will show abnormally increased factor VIII coagulant activity and diminished antithrombin III levels. Abnormalities in fibrinolysis do not appear to be common.[592] In addition to this, factor XI and factor XII levels are higher in some diabetic patients with evidence that the kallikrein-prekallikrein system has been activated.[593] Ketoacidosis may be associated with DIC.[594] Altered levels of factors V and VIII and diminished fibrinolytic activity have been reported in a few patients.[595]

The hematologic consequences of diabetes also extend to infants born of diabetic mothers. An increased incidence of thrombosis or thromboembolic phenomena is well recognized in these infants.[596] Complications such as renal vein thrombosis, peripheral gangrene secondary to vascular occlusion, and cerebral thrombosis may occur.[597]

METABOLIC DISEASES

Discussion in this section is restricted mainly to the hematologic consequences of the lipid disorders of metabolic origin. The hematologic findings of the other storage disorders and metabolic diseases are covered in Chapter 25 and throughout the book.

Disorders in Lipid Metabolism

Tangier Disease

Tangier disease, caused by mutations in the gene encoding ATP-binding cassette 1 *(ABCA1)*, is a rare autosomal recessive condition in which homozygotes have splenomegaly, absent or very low levels of high-density lipoproteins (HDLs), reduced levels of low-density lipoproteins (LDLs) (typically 40% of normal), hypertriglyceridemia, mild corneal clouding, peripheral neuropathy, bone marrow foam cells (70% of patients), and characteristic orange cholesterol ester–laden tonsils.[598] *ABCA1* is a major determinant of plasma HDL cholesterol and is critically involved in cellular trafficking of cholesterol and choline phospholipids. *ABCA1* mediates the first step in reverse cholesterol transport, the transfer of cholesterol and phospholipids to lipid-poor apoproteins.[599,600] Cholesterol ester levels are greatly elevated in tissue macrophages in Tangier disease owing to the lack of HDLs, which normally return cholesterol esters to the liver. The HDL deficiency is caused by hypercatabolism of the lipoprotein. Normally, HDLs bind to specific receptors on macrophages, are internalized (presumably to load up on cholesterol esters), and then recycle to the membrane surface. In Tangier disease, HDLs are misrouted to macrophage lysosomes and destroyed.

Hematologic examination of one patient with Tangier disease demonstrated stomatocytosis, hemolysis (hemoglobin concentration of 8.5 g/dL; reticulocyte count of 6 to 9%), and osmotically sensitive red blood cells.[601] Because hematologic data have rarely been reported in patients with Tangier disease, it is difficult to be certain that this patient's data are not exceptional. However, previous reports of unexplained hemolysis in three patients suggest that they are not.[602-604]

Familial Lecithin-Cholesterol Acyltransferase Deficiency

Familial lecithin-cholesterol acyltransferase (LCAT) deficiency is a rare autosomal recessive disorder characterized by anemia, corneal opacities, hyperlipemia, proteinuria, chronic nephritis, and premature atherosclerosis.[605,606] LCAT deficiency is relatively asymptomatic during childhood. Proteinuria and corneal opacities are among the earliest manifestations. The latter consist of minute grayish dots that concentrate near the edge of the cornea, resembling arcus senilis. Almost all of the reported patients have had a moderate normochromic anemia (hemoglobin level of 8 to 11 g/dL) characterized by prominent target cell formation and decreased osmotic fragility.[607,608,609]

Hematologic studies in LCAT deficiency suggest that the anemia is due to a combination of moderate hemolysis and decreased erythropoietic compensation, but interpretation of the evidence is complicated by the coexisting renal disease. Other studies have shown that the red blood cells are abnormally susceptible to peroxidative threat and have mechanically fragile membranes.[608] There is no obvious explanation for these changes, but it is possible that they contribute to the shortened red blood cell life span. LCAT deficiency is caused by a variety of mutations in the *LCAT* gene; affected individuals are either homozygotes or compound heterozygotes for these mutations.[609,610]

Modeling of the mutations has provided insight into *LCAT* structure and function.[611] As expected from the absence of LCAT activity, there is a pronounced decrease in cholesteryl esters and an increase in free cholesterol and phosphatidylcholine in plasma lipoproteins. Because LCAT is required for normal lipoprotein formation and catabolism, nascent lipoproteins and abnormal lipoprotein remnants accumulate in the plasma. One of the latter is LP-X, which is believed to be responsible for target cell formation in patients with the acquired LCAT deficiency of obstructive liver disease.[612] Free cholesterol and phosphatidylcholine levels are markedly elevated in the red blood cell membranes of patients with LCAT deficiency; however, total red blood cell phospholipid levels are normal because the increase in phosphatidylcholine is balanced by a decrease in phosphatidylethanolamine and sphingomyelin.[605] As with liver disease, red blood cell targeting and lipid abnormalities can be induced by incubation of normal red blood cells in LCAT-deficient lipoproteins and reversed by incubation in normal serum.[613] Other plasma membranes are also probably affected by the abnormal LCAT-deficient lipoproteins. For example, accumulations of lipid in endothelial membranes may underlie the atherosclerotic and nephritic complications seen in some patients. Phagocytosis of abnormal lipoproteins by reticuloendothelial cells leads to the appearance of foam cells and sea-blue histiocytes in the bone marrow, spleen, and other organs.[607,614] Serum and red blood cell lipids are improved in vivo when LCAT is supplied by infusions of normal plasma; however, the short half-life of this protein, 4 to 5 days, and the large amounts of plasma required make chronic replacement therapy impractical.

Fish-Eye Disease

Fish-eye disease is caused by partial deficiency of LCAT and is also associated with mutations in the *LCAT* gene.[605,609] It is characterized by corneal opacities (which give the disease its name), hypertriglyceridemia, and very low levels of HDLs. One report noted increased target cells and decreased osmotic fragility.[615]

Other Metabolic Disorders

Cystinosis is a rare lysosomal storage disorder associated with poor growth, proximal tubular renal Fanconi syndrome with associated electrolyte and protein loss, and complications from cystine accumulation in various organs, including the reticuloendothelial organs and corneal tissues.[616] All forms of cystinosis are caused by mutations in the *CTNS* (cystinosin, lysosomal cystine transporter) gene, with more than 80 mutations reported. Diagnosis can be established by demonstrating cystine crystals in macrophages of the bone marrow (Fig. 37-15). In rare cases, cystine can accumulate to cause bone marrow failure with pancytopenia.

Primary oxaluria, caused by overproduction of oxalate, is an autosomal recessive disorder associated with failure

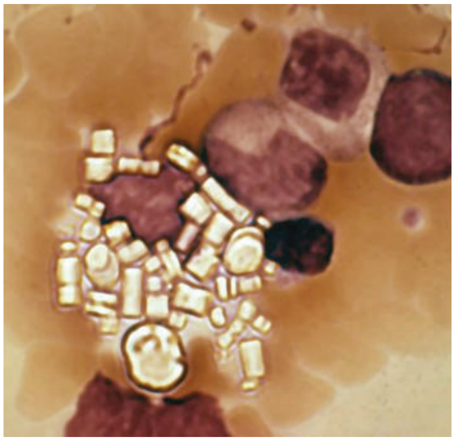

Figure 37-15 Cystine crystals in a macrophage of the bone marrow in a patient with cystinosis.

to thrive, urolithiasis, renal failure, and complications from oxalate accumulation in the joints, retina, skin, heart, and bone marrow.[617] Diagnosis can be made by measuring urinary oxalate, genetic testing, and/or bone marrow biopsy.

Osteopetrosis is a heterogenous group of disorders caused by defective osteoclastic resorption of bone with associated increased bone density. Childhood forms are typically more severe and often linked to autosomal recessive mutations in the *TNFSF11* (tumor necrosis factor [ligand] superfamily, member 11; formerly *RANKL*) gene.[618] Symptoms include fractures, short stature, pancytopenia due to bony expansion, and resultant hepatosplenomegaly from extramedullary hematopoiesis.

Essential fatty acid deficiency will result in a variety of characteristic changes in plasma lipids. Decreased prostaglandin formation in in vitro platelet studies involving animals with essential fatty acid deficiency has been reported.[619] This results in impaired platelet aggregation and may reflect a deficiency of arachidonic acid necessary for the formation of thromboxane A_2.[619] Clinically, essential fatty acid deficiency is being recognized more often as a result of prolonged fat-free parenteral nutrition.[620] Several infants have been described with hemorrhagic complications from this disorder.[619]

A child has been described with altered vitamin B_{12} metabolism in association with megaloblastic anemia and homocystinuria secondary to a defect in methionine biosynthesis.[621] Homocystinuria and megaloblastic anemia responsive to vitamin B_{12} therapy have also been reported as an inborn error of metabolism caused by a defect in cobalamin metabolism.[622] Infants and children with orotic aciduria, hyperglycinemia, and hyperglycinuria may have neutropenia.[623] Patients with orotic aciduria may also exhibit megaloblastic changes in bone marrow and have macrocytic indices.

NEUROLOGIC AND PSYCHIATRIC DISORDERS

Discussion in this section relates to the hematologic findings in the neuroacanthocytoses and anorexia nervosa. Neuroacanthocytosis refers to a group of diseases in which neurologic changes are found in the setting of acanthocytes in the peripheral blood smear.[624,625] In some cases of neuroacanthocytosis, acanthocytes are not detected on the peripheral smear. However, because routine genetic testing and classic laboratory findings are not available for most of these disorders, the detection of acanthocytes is one of the hallmarks of clinical diagnosis. The most sensitive and specific method for measuring acanthocytes is using isotonically diluted blood combined with unfixed wet blood preparation with the normal range of less than 6.3% acanthocytes of the total erythrocytes.[626] The mechanism of acanthocyte formation in the individual subsets of the neuroacanthocytoses is related to specific membrane protein defects, including band 3 and the XK protein of the 4.1 multiprotein complex.[627,628,628a] The subsets of neuroacanthocytoses are abetalipoproteinemia, McLeod syndrome (reviewed in Chapter 36), chorea-acanthocytosis, Huntington disease–like 2, and pantothenate kinase–associated neurodegeneration.

Neuroacanthocytoses

Abetalipoproteinemia

Abetalipoproteinemia (Bassen-Kornzweig syndrome) is an autosomal recessive disorder that causes a failure to synthesize or secrete serum apolipoprotein B–containing lipoproteins. With the lack of apolipoprotein B there is defective intestinal absorption of lipids and extremely low serum cholesterol and triglyceride levels.[629] Owing to deficient absorption of fat-soluble vitamin E, individuals with abetalipoproteinemia develop severe, but often reversible, neurologic problems, such as spinocerebellar degenerative ataxic disorder with peripheral neuropathy and retinitis pigmentosa leading to blindness.[630,631] These findings are also associated with the presence of acanthocytic red blood cells. The cholesterol content of the red blood cell is normal or slightly increased, whereas the phospholipid content reflects that of serum.[629] Autohemolysis[632] and peroxidative hemolysis[633] may be increased, but osmotic fragility[632] and rates of glycolysis[632] are normal. Anemia, if present, is mild.

This rare disease is caused by various mutations in the microsomal triglyceride transfer protein gene *(MTTP)*, which catalyzes the transport of triglyceride, cholesterol ester, and phospholipid from phospholipid surfaces.[634,635] MTTP forms a heterodimer with a multifunctional protein called disulfide isomerase, which is located in the lumen of hepatic microsomes and intestinal epithelia, the sites of lipoprotein synthesis.[636-638] Disulfide isomerase is the only tissue-specific component, other than apolipoprotein B, required for secretion of apolipoprotein B–containing lipoproteins.[639]

Related entities (hypobetalipoproteinemia, normotriglyceridemic abetalipoproteinemia, and chylomicron retention disease) exist that are associated with partial production of apolipoprotein B–containing lipoproteins or with secretion of lipoproteins containing truncated forms of apolipoprotein B. Patients with these diseases may also manifest acanthocytosis and neurologic disease, depending on the severity of the lipoprotein defect. The majority of patients with heterozygous hypobetalipoproteinemia do not have acanthocytosis.

Characteristically, 50% to 90% of the red blood cells are acanthocytes (Fig. 37-16).[640] The shape defect is not evident in nucleated red blood cells or reticulocytes and worsens as the erythrocytes age. Membrane protein composition is normal, but membrane lipid composition is not. Phosphatidylcholine concentration is decreased by about 20%, and the amount of sphingomyelin is correspondingly increased. The cholesterol-to-phospholipid ratio is normal to mildly elevated.[641-643] These changes reflect abnormalities in the distribution of plasma phospholipids and a decrease in LCAT activity.[644] The relative increases in cholesterol and sphingomyelin concentration both decrease lipid fluidity, particularly in the outer one half of the bilayer, and presumably contribute to the acanthocytic shape.[642]

Because of fat malabsorption and the absence of LDLs, which transport vitamin E, the red blood cells of these patients are markedly deficient in vitamin E.[645,646] Oxidant sensitivity can be prevented by treatment with a

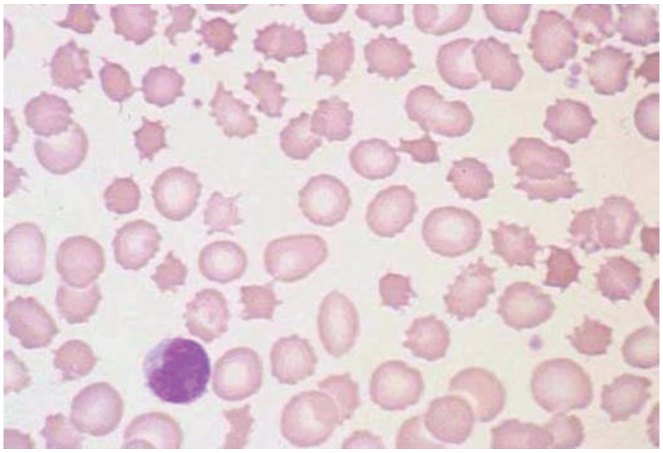

Figure 37-16 Acanthocytosis in abetalipoproteinemia.

water-soluble form of vitamin E (e.g., D-α-tocopherol polyethylene glycol succinate).[646] Despite increased lipid viscosity and vitamin E deficiency, the hemolysis experienced by these patients is mild.[641]

Patients with familial hyperbetalipoproteinemia (type II hyperlipoproteinemia) have abnormal platelet function[647] characterized by increased sensitivity to aggregating agents and release of increased amounts of nucleotides in response to aggregating agents. These changes are associated with platelet plasma membrane ultrastructural changes, particularly in type IIa hypercholesterolemia.[648] Such subjects may truly demonstrate a "hypercoagulable state." The latter has been demonstrated in severely hypertriglyceridemic conditions.[649] These findings suggest the possibility that platelet function may be involved in the thrombotic complications of familial hyperbetalipoproteinemia.

Chorea-Acanthocytosis

This syndrome was first described by Estes and colleagues.[650,651] Since then, this autosomal recessive disorder has been well characterized as a progressive movement disorder with acanthocytosis, myopathy, and cognitive and behavior changes beginning in adolescence or adult life (8 to 62 years).[652] The movement disorder is most typically characterized by limb chorea, but also can present as parkinsonism, orofacial dyskinesia, lip and tongue biting, involuntary vocalizations leading to mutism, seizures, and decreased or absent tendon reflexes.[653,654] The lingual-buccal-facial dyskinesia and oral self-mutilation are most characteristic of chorea-acanthocytosis. The myopathy causes distal muscle wasting and hypotonia, as well as increased levels of creatine phosphokinase. The extent of mental deterioration varies but often resembles that of the frontal lobe syndrome.[655]

The mutant protein in chorea-acanthocytosis, chorein, encoded by the vacuolar protein sorting 13 homolog A gene *(VPS13A)* on chromosome 9q21, has been identified and over 70 different mutations have been reported.[656-659] The function of chorein is unknown, but *VPS13A* is a member of a conserved gene family involved in membrane protein trafficking. The loss of chorein may be diagnostic for this disorder, because it is not seen in similar disorders, such as Huntington disease or McLeod syndrome.[658,660] Genetic testing is commercially available but is difficult owing to the large gene size and the heterogeneity of mutations. The diagnosis of this disorder is still often made through radiologic and clinical findings, as well as evidence of muscle disease. Magnetic resonance imaging (MRI) and pathologic examinations show atrophy of the basal ganglia, particularly the caudate and putamen. In some patients, little or no hemolysis occurs; in others, acanthocytosis precedes the onset of neurologic symptoms.[655] In others, acanthocytes do not appear until late in the disease course.[661] In some patients, splenomegaly is noted, likely owing to hemolysis.[661] Multiple red cell alterations have been described in the acanthocytes of patients with Choreacanthocytosis.[628a] On electronic microscopy, these red cells have a heterogeneous distribution of membrane skeleton. An increased amount of gamma-glutamyl lysine isopeptide is associated with the membrane in some patients. Choreacanthocytic red cells have a perturbation of the skeletal network, which may lead to the instability in bridging band 3 protein complexes in the absence of chorein. These red cells have a reduced response to drugs, inducing endovesicles.[628b]

Of note, one family has been described with a defect near the COOH-terminal end of band 3, Pro868Leu.[662] Hematologically, affected individuals of this kindred have 20% to 25% acanthocytes and mild anemia with reticulocytosis. However, this family's defect seems to be a distinct disorder separate from the more typically described chorea-acanthocytosis.

Huntington Disease–like 2

In 2001, Margolis and associates described a pedigree with an autosomal dominant, Huntington-like disease due to CAG/CTG repeats in a novel site.[663] Huntington disease–like 2 has since been characterized as a hyperkinetic disorder similar to Huntington disease that mostly or exclusively affects patients of African ancestry. This neuroacanthocytosis typically is manifested in the third decade by weight loss, dystonia, rigidity, chorea, behavioral changes, and acanthocytosis.[664,665] Acanthocytosis in this disorder may be related to involvement of small G proteins in membrane skeletal rearrangement.[628a] Brain imaging demonstrates marked striatal atrophy and moderate cortical atrophy, similar to Huntington disease. The CTG/CAG trinucleotide repeat expansion has been found within a variably spliced exon on the junctophilin 3 gene *(JPH3)* on chromosome 16q24.3.[666]

Pantothenate Kinase–Associated Neurodegeneration

This autosomal recessive progressive movement disorder is caused by a mutation in the pantothenate kinase 2 gene *(PANK2)* on chromosome 20p13.[667,668] In the classic form of this neuroacanthocytosis, patients present within the first decade of life with a rapidly progressive motor disease leading to loss of ambulation. The atypical and intermediate forms present later in life and progress more gradually. Individuals with an earlier onset of symptoms typically develop pigmented retinopathy. Those with a later onset tend to also develop psychiatric and speech disorders. The motor disease is characterized by rigidity in the lower and, later, the upper extremities. Choreic type movements often coincide with the rigidity. Owing to the effects on voluntary movement and muscular tone, patients also develop difficulty chewing and swallowing.[669] Ten percent of patients have acanthocytes on the peripheral smear.

The diagnosis of this disorder is made clinically and radiologically. Brain MRI pallidal abnormalities, described as the "eye of the tiger" sign, consist of decreased signal intensity in T2-weighted images, compatible with iron deposits, and of a small area of hyperintensity in the internal segment.[670] All patients with this disorder have the "eye of the tiger" sign on brain MRI.[671,672] However, this sign is not specific only to pantothenate kinase–associated neurodegeneration.[671,673] Historically, this disease was referred to as Hallervorden-Spatz disease, named after Julius Hallervorden and Hugo Spatz who originally described this disorder. In 2001, Zhou and colleagues suggested this disorder be referred to as pantothenase kinase–associated neurogeneration to avoid the objection to its eponym, because Hallervorden and Spatz were able to make their original descriptions of this disorder by actively participating in the euthanasia program in Germany during World War II.[668]

Anorexia Nervosa

Patients with anorexia nervosa may demonstrate many of the hematologic manifestations of severe malnutrition with concomitant vitamin B_{12}, folate, and iron deficiency as well as more rare nutritional deficiencies. Normochromic, normocytic anemia will be present in 20% to 30% of patients with anorexia.[674] Acanthocytosis is common in patients with severe anorexia nervosa (Fig. 37-17).[674,675] The cause of the acanthocytosis is unknown. Plasma lipid and LDL levels are typically normal or slightly decreased. However, even in those patients with low levels of LDLs, acanthocytosis may not be due solely to the lipoprotein deficiency, because patients with much lower concentrations of LDLs (e.g., those with hypobetalipoproteinemia) usually have normal red blood cell morphology.[676] Red blood cell life span is normal or only slightly shortened. Severe starvation or malnutrition due to causes other than anorexia nervosa can also produce acanthocytosis or target cells and hypobetalipoproteinemia.[677]

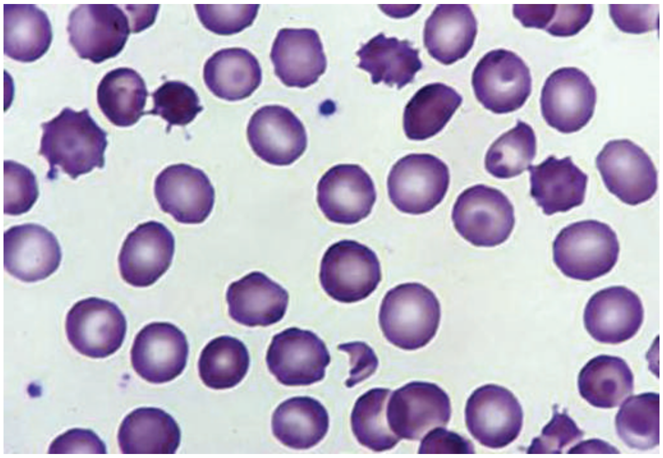

Figure 37-17 Acanthocytosis in anorexia nervosa.

Leukopenia and neutropenia are common, and this may be associated with an increased risk for infection.[678] Leukocyte response to bacterial infection may be suboptimal. Mild thrombocytopenia is often seen.[674,675,679-681] A marked increase in platelet hyperaggregability may be found.[682] In addition to specific nutrient deficiencies, cytopenias can also be due to a hypoplastic bone marrow filled with gelatinous material.[683,684] Several months may be needed for the blood cell abnormalities in anorexia nervosa to resolve after adequate caloric intake.

CUTANEOUS DISEASES

Skin diseases are only rarely a direct cause of hematologic disturbances. More often than not, the hematologic alterations reflect a simultaneous disturbance in more than one developmental system, such as the skin and blood. Certain disorders that affect the hematologic system and the skin, such as Wiskott-Aldrich syndrome, are described in Chapter 24.

Eczema and Psoriasis

Patients with extensive eczema or psoriasis commonly have a mild anemia.[685] The anemia is usually normochromic and normocytic, although microcytosis may occur. Typically, this anemia is associated with a low serum iron level and normal or decreased iron-binding capacity and best classified as an anemia of chronic disease.[685] A defect in red blood cell deformability in eczematous patients has been reported.[686] Some individuals with extensive rash will have greatly expanded whole blood and plasma volumes, which may result in a dilutional anemia.[687,688] In rare patients with eczema or psoriasis, long-standing steatorrhea may develop and cause folate malabsorption and macrocytic anemia.[689] Psoriasis may be a widespread membrane disorder. Alterations in red blood cell sodium and potassium fluxes are seen, as well as alterations in membrane lipid composition (an increase in arachidonic acid and unsaturated fatty acid content).[690,691] The increased erythrocyte membrane arachidonate and platelet malondialdehyde production noted in patients with psoriasis may normalize after treatment with fish oil.[692]

Hereditary Hemorrhagic Telangiectasia

This inherited structural abnormality of the vasculature is characterized by mucocutaneous telangiectases caused by localized dilation and convolution of venules and capillaries. It is an autosomal dominant disorder that results in a bleeding tendency because of the friable blood vessels. Telangiectases predominate on the lips, buccal mucosa, gingivae, palate, tongue, and skin of the face and upper parts of the body and may be present in visceral organs as well. Pulmonary arteriovenous fistulas are not rare but tend to appear later in life. Easy bruisability, epistaxis, and respiratory and gastrointestinal bleeding may be caused by these telangiectases.

Mast Cell Disease

In mast cell disease, large numbers of mast cells are found, often diffusely located in the skin or the gastrointestinal tract.[693] These cells periodically release histamine and heparin-like substances.[693,694] Trauma to involved areas may trigger release of these substances and may also cause urticaria and blistering of affected parts of the body. A bleeding diathesis can be caused by mast cell disease due to an increased systemic heparin concentration and/or an increased fibrinolysis by tissue plasminogen activator release.[695] Because fatal hemorrhage may result from this excessive anticoagulant effect, treatment with protamine sulfate may be necessary.

Systemic mast cell activation can occur with systemic mastocytosis, in which clonal CD25 positive mast cells typically carry an activating *KIT* point mutation D816V.[696] In systemic disease, mast cells may infiltrate the bone marrow and cause cytopenias. *KIT* D816V can also be expressed in mast cells in patient with cutaneous mastocytosis. Serum tryptase is often elevated in these conditions.

Urticaria pigmentosa is one form of mast cell disease. On rare occasion, mast cell disease and urticaria pigmentosa precede the onset of mast cell leukemia.[697]

PREGNANCY

Pregnancy, with a reorientation of the mother's physiology to support the expanding growth of the fetus, is frequently complicated by hematologic disorders. Some of these arise from the progressive hypercoagulable state of pregnancy,[698] in preparation for placental separation, whereas other disorders result from pathologic initiation of the clotting cascade secondary to the release of placental, amniotic, or fetal elements.[699] Antecedent hematologic disorders are compounded by the demands of pregnancy and may be exaggerated in severity and impact because of their dual effect on mother and fetus. Management of these conditions must also take into account the effect that any hematologic defects or medications used to reverse these defects may have on the fetus. A detailed review of the hematologic manifestations of pregnancy is beyond the scope of this pediatric textbook, but a broad overview of the types of hematologic findings is provided in this section.

Anemia of Pregnancy

During the first and second trimesters of pregnancy, a physiologic expansion of the mother's plasma volume occurs, which outdistances a concomitant increase in the red blood cell mass.[699] The plasma volume starts to increase at about 6 weeks and reaches about 1250 mL at term, an increase of about 50% above the nonpregnant state.[700] The red blood cell mass increases about 20%, or 250 mL, without iron supplementation and may reach 400 mL with iron supplements. This increase in plasma volume results in a reduction in the normal woman's hemoglobin and hematocrit. The hemoglobin nadir is 11.4 ± 0.8 at 25 to 26 weeks of gestation, which makes the minimum value (–2 SD) 9.8 g/dL.[701] In general, the minimum hemoglobin value is 11 g/dL in the first trimester and 10 g/dL in the next two trimesters.[702,703]

A number of studies show a relation between prematurity, low birth weight, and maternal anemia.[704-709] One large epidemiologic study found that the risk for premature delivery increased by 20% in pregnancies in which the hemoglobin value is between 10 and 11 g/dL and by 60% when it was in the 9- to 10-g/dL range.[707] Below 9 g/dL the risk doubled and tripled for each additional decrease of 1 g/dL. Another study found that perinatal mortality tripled when the mother's hemoglobin level decreased below 8 g/dL.[709]

On the other hand, there is evidence that the normal expansion of maternal plasma volume is needed for an optimal pregnancy outcome.[710] Several studies demonstrate a positive correlation between the weight of the neonate and the increase in plasma volume within the normal range.[710-714] Whether the increase is needed for optimal fetal oxygenation and growth or whether normal fetal growth somehow triggers the increase is not known. However, high hemoglobin levels portend pregnancy complications, such as fetal growth restriction, premature birth, pregnancy-induced hypertension, and perinatal fetal distress or death.[715-718] For example, the frequency of hypertension in primiparas with hemoglobin levels less than 10.5 g/dL is only 7% but rises to 42% when the hemoglobin concentration is more than 14.5 g/dL.[710]

The surge in red blood cell production during pregnancy, even though less than the plasma volume, often outstrips the marginal iron and folate stores of the expectant mother. Iron deficiency accounts for about 75% of the anemias in women who do not take iron supplements. It is estimated that about 80% of pregnant women who do not take iron supplements will have hemoglobin values less than 11 g/dL at term.[719] The consequences to the fetus are less certain. Some investigators observe a direct relationship between maternal and fetal iron levels; others find that the level of iron in the mother has little effect on that in the neonate.[720,721] The fetal demands seem to dominate. Mild to moderate iron-deficiency anemia in the mother does not cause significant anemia in the fetus.[720]

Folic acid deficiency is estimated to exist at term in 60% to 95% of pregnant women who have not taken folate supplementation,[719] although frank megaloblastic anemia is uncommon. Folate deficiency predisposes to devastating defects in closure of the neural tube and thus in spinal cord development,[722-724] but folate supplementation to prevent this malformation must be given before conception because neural tube closure occurs during the fourth week of embryogenesis. The risk for neural tube defects is higher in mothers with the common thermolabile variant of 5,10-methlyenetetrahydrofolate reductase,[725] which impairs enzyme activity and raises blood levels of homocysteine.

Low values of serum iron (<30 μg/dL) and ferritin (normal values in pregnancy 55 to 70 μg/L) are reliable indicators of iron deficiency.[702] Reliance on a low mean corpuscular volume (MCV) measurement may be misleading during pregnancy because a combined deficiency may cancel out the extremes of iron (low MCV) and folate (high MCV) deficiency.[726] To avoid the development of anemia secondary to these deficiencies, it is standard practice to supplement all pregnant women with prenatal vitamins with iron and folate. For those women who cannot tolerate iron, monitoring of serum ferritin permits assessment of iron stores and the specific need for iron supplementation.[727]

Other causes of anemia during pregnancy are much rarer. An aplastic anemia that resolves with abortion of the fetus and recurs with subsequent pregnancies is presumed to have an immunologic basis when it occurs during pregnancy.[728] The devastating anemia secondary to intravascular hemolysis that is associated with clostridial sepsis may be a lethal complication of septic abortions.[729]

Thrombocytopenia of Pregnancy

With its potential to exaggerate bleeding during the birth process, thrombocytopenia needs careful assessment and management in the pregnant woman.[730] Thrombocytopenia, with a platelet count less than 100 kcells/μL is observed in 1% of pregnant women.[731] The incidence of all of the classic thromboconsumptive processes of ITP, TTP, and DIC is increased during pregnancy and is joined by platelet abnormalities as a component of eclampsia of pregnancy.[732] The diagnosis of ITP during pregnancy requires the same constellation of findings as that in the nonpregnant state.[731,733] Because the antibodies in ITP cross the placenta and may create thrombocytopenia in the infant, this condition can create problems for the mother and fetus.[734]

The mechanism of thrombocytopenia in eclampsia is not certain.[735] The fact that the low-dose aspirin prevents the perinatal consequences of preeclampsia in high-risk mothers[736,737] suggests a platelet-endothelial defect may underlie the disease. The spectrum of toxemia has been extended to include the HELLP syndrome (*h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets), which may or may not be accompanied by the more classic evidence of toxemia.[738-740] The disease occurs in 0.2% to 0.9% of pregnancies, typically at between 32 and 34 weeks of gestation, although it occurs after delivery in 30%.[740] The cardinal clinical symptom is right upper quadrant or epigastric pain with nausea, vomiting, or malaise. The disease often progresses to a life-threatening state. Management of the hematologic problems of toxemia and HELLP syndrome entails management of the toxemia state, which frequently requires delivery of the infant if the maturity of the fetus allows.

Disseminated Intravascular Coagulation and Pregnancy

Because the products of conception can initiate the coagulation cascade when released into the maternal circulation, the course of pregnancy and delivery are not infrequently accompanied by DIC. DIC is covered in detail in Chapter 35. Fetal death in utero,[741] abruptio placentae,[742,743] and amniotic fluid embolism[744] all are often signaled by bleeding or coagulation abnormalities. Management of these abnormalities requires delivery of the fetus while providing blood component therapy with platelets, fresh-frozen plasma, and cryoprecipitate to replace the consumed elements. Amniotic fluid embolism has the especially threatening complication of cardiopulmonary collapse, which requires cardiopulmonary support and corticosteroids in addition to blood product administration.[745] DIC may also accompany the severe hemolytic anemia that occurs when clostridial sepsis follows an abortion.

Sickle Cell Disease and Pregnancy

The management of sickle cell during pregnancy is covered in Chapter 20.

Inherited Bleeding Disorders and Pregnancy

Neither of the classic hemophilic syndromes complicates pregnancy because of their X-linked mode of inheritance. von Willebrand disease does require recognition, although the incidence of bleeding secondary to this problem in pregnancy is mitigated by the physiologic increase in factor VIII and von Willebrand factor during pregnancy. Treatment of bleeding due to von Willebrand disease consists in the use of von Willebrand factor concentrate or, for short-term control of bleeding, infusions of desmopressin.[746] The latter may normalize von Willebrand factor levels in the various subgroups of von Willebrand disease, although its use in type IIB disease may lead to thrombocytopenia owing to release of abnormal von Willebrand factor in this group.[747] Dysfibrinogenemias and factor XIII deficiency are both associated with spontaneous abortions and abnormal bleeding; plasma infusions throughout pregnancy may be successful in averting complications in these groups.[748]

Pregnancy and Thrombosis

Pregnancy represents a progressive hypercoagulable state during which a marked increase in the incidence of venous thrombosis is seen.[749,750] Venous thromboembolism is the leading cause of maternal mortality during pregnancy in Western countries. Low-molecular-weight heparin is used to prevent and/or treat thrombosis in pregnancy.[751,752] The drug is discontinued at the time of delivery but reinitiated 24 hours after delivery because of the ongoing risk for thrombosis that persists for 8 to 12 weeks after delivery. Warfarin (Coumadin) is avoided during pregnancy, especially during the first trimester, because of the risk for an embryopathy. Heparin escapes this complication because it does not cross the placenta, although it is associated with the threat of bleeding and fetal loss. Either can be used in the postpartum period because neither drug creates problems for the nursing mother or infant.[753,754]

Inherited Hypercoagulable States and Pregnancy

The inherited thrombophilic disorders are covered in Chapter 33. Women who inherit defects in these proteins are more likely to experience fetal loss, particularly stillbirths, than controls.[755] The risks are greatest in antithrombin III deficiency and in women with more than one inherited risk factor. These defects also appear to play a role in other gestational vascular complications, including fetal growth restriction, preeclampsia, and placental abruption.[755,756] Many women with a personal history of venous thrombosis, three unexplained miscarriages, abruptio placentae, stillbirths, or recurrent fetal growth restriction are screened for inherited thrombophilias. Current guidelines suggest that women with recurrent early pregnancy loss should be screened for antiphospholipid antibodies, but women with a history of other pregnancy complications but no history of thrombosis should not be screened for an inherited thrombophilia.[752]

Antiphospholipid Antibody Syndrome and Pregnancy

Antiphospholipid antibodies and the antiphospholipid antibody syndrome are discussed in Chapters 29 and 35. In addition to the risk for venous and arterial thrombosis, pregnant women with antiphospholipid antibodies have an increased risk for fetal loss, premature delivery, preeclampsia, and uteroplacental insufficiency.[757] The risk to the pregnancy involves all periods: preembryonic (<6 weeks), embryonic (6 to 9 weeks), and fetal (≥10 weeks). The mechanisms are not well defined but may include antiphospholipid antibodies interfering with binding of the protective anticoagulant annexin V to phospholipid surfaces on endothelial cells and trophoblasts.[758]

Prospective trials show that heparin plus low-dose aspirin is more effective than aspirin alone in achieving live births in pregnant women with antiphospholipid antibodies and predominantly preembryonic and embryonic loss.[752,759] Doses of heparin sufficient to produce full anticoagulation are recommended for all women with antiphospholipid antibodies and prior thromboembolism.

TOXINS AND OTHER INSULTS

Toxins, venoms, and thermal injury can cause marked disturbances in hematopoiesis. The most common and extensively described toxin is alcohol. The hematologic complications of snake bites are covered in Chapter 38.

Alcohol and Hematopoiesis

Significant hematologic damage is incurred by alcoholics because of the combined direct toxicity of alcohol on the marrow and the multiple associated abnormalities in the nutritional and gastrointestinal systems that exist in the alcoholic.[760] Alcohol supplies empty calories for nutrition and is also frequently accompanied by multivitamin deficiencies; alcohol-induced gastritis is threatened with a double jeopardy for bleeding imposed by the combination of thrombocytopenia and a qualitative platelet dysfunction created by the toxin.[761] Congestive splenomegaly, as an accompaniment to both acute alcoholic fatty liver and chronic cirrhosis, may further deplete the red blood cell pool. These myriad potential pathologic contributions of ethanol to hematopoiesis and its environment readily explain the frequent occurrence of anemia in about 50% of patients hospitalized with acute or chronic alcoholism.[762]

Alcohol and the Red Blood Cell

Heavy alcohol ingestion of over 1 week's duration produces a characteristic vacuolization of the red blood cell precursors in the marrow, a finding shared with chloramphenicol toxicity, phenylalanine deficiency, and hyperosmolar states (Fig. 37-18).[763] More chronic ingestion of lesser amounts of alcohol results in a mild macrocytosis unaccompanied by any megaloblastic features in the marrow.[764]

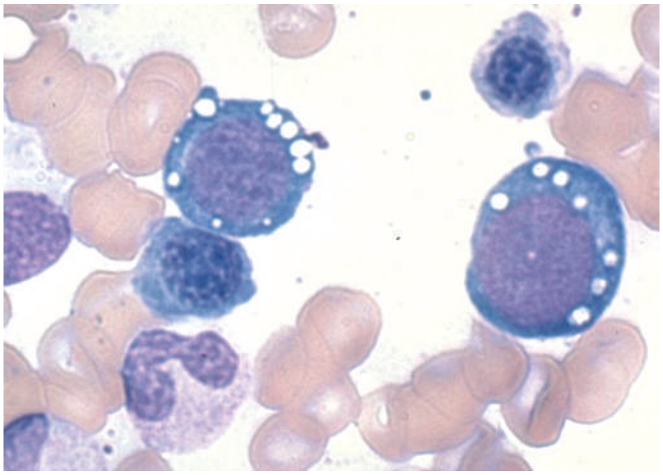

Figure 37-18 Vacuolated normoblasts in the bone marrow of a patient with alcoholism.

Evaluations of adults with macrocytosis (MCV >100 fL) show that alcohol is one of the most common causes, along with drugs and liver disease, especially alcoholic liver disease.[765,766] Surprisingly, only about 10% of patients with macrocytosis have megaloblastic anemias, although the fraction increases greatly at higher MCVs (>120 fL). In fact, a high or high normal MCV (>94 fL) is one of the best screening tests for identifying hazardous drinkers in general practices.[767]

The vacuolization of normoblasts is short-lived (3 to 5 days) after ethanol withdrawal, whereas the macrocytosis of alcoholism persists for 1 to 2 weeks after abstinence from the toxin.[768] The mechanism for the production of these abnormalities is not well established. Vacuolization may just be a nonspecific sign of injury. It occurs with chloramphenicol toxicity and in diseases associated with erythroblast damage, such as parvovirus B19 infection.

Macrocytosis can also be due to folic acid deficiency, which is common in alcoholics, but macrocytosis may also be a consequence of bone marrow toxicity by alcohol, because it occurs in response to any reversible bone marrow injury. During recovery from such damage, the bone marrow releases "stress" erythrocytes, which have some of the characteristics of fetal red blood cells, including large size, increased fetal hemoglobin, and the i antigen. Finally, hemolysis and bleeding must always be considered in the evaluation of macrocytosis, because reticulocytes have a much higher MCV than mature erythrocytes.

Acquired stomatocytosis is another red blood cell abnormality that is common in alcoholics, particularly in those with acute alcoholism, and it may be associated with moderate hemolysis.[769] In one study, 15% of alcoholic patients had marked stomatocytosis (≥10% stomatocytes) and 29% of the patients had 3% to 9% stomatocytes.[770] The MCV was significantly higher in these patients.

Ethanol is also a direct toxin to hematopoietic cells with evidence that ethanol and its breakdown product, acetaldehyde, both inhibit erythroid marrow colony growth in vitro.[771] A further insult to erythropoiesis is produced by a direct antifolate effect of alcohol on the marrow; this compounds an already reduced availability of folate due to alcohol's interference with the normal enterohepatic recirculation of folate and decreased amounts of the active congener of folate, methyl tetrahydrofolate.[772,773] The sum of these insults to folate metabolism is escalated further by the simultaneous presence of folate deficiency as a result of a poor diet, producing megaloblastic anemia as the most common form of anemia in alcoholics.[774]

The megaloblastic transformation of the marrow due to folate deficiency may not be accompanied by the anticipated striking macrocytosis in the peripheral blood because the condition is often compounded by iron deficiency. This frequently produces a dimorphic red blood cell picture in which there exists competing contributions of both deficiencies to red blood cell size. Hypersegmentation of the polymorphonuclear cells still remains as a marker of megaloblastic hematopoiesis, an important clue when macrocytosis has been blunted by iron deficiency.[775] Measurement of red blood cell folate confirms the deficiency, one that may occur in the course of only a few weeks of a folate-deficient diet.

Megaloblastic transformation of the marrow is frequently further complicated by ringed sideroblast formation in which iron accumulates in and around altered mitochondria in red blood cell precursors.[776] This iron fails to be normally incorporated into heme, and the red blood cell products of this pathway are hypochromic in the presence of iron-overloaded mitochondria. The defect originates in alcohol's direct interference in protoporphyrin ring synthesis or in a toxic effect of alcohol on the mitochondria. These insults to normal hemoglobin production and the ineffective hematopoiesis characteristic of megaloblastic lesions alter iron kinetics within the body.

After alcohol intake has been discontinued and nutritional supplements provided, the megaloblastic component of the anemia is rapidly reversed. Serum iron levels plummet as normal erythropoiesis supervenes. Sideroblastic features persist for 7 to 10 days, a more prolonged aftermath of alcohol toxicity. The marrow, freed from alcohol's suppressive effect, responds with a reticulocytosis that has frequently been misinterpreted as evidence for hemolysis in the jaundiced, anemic drinker. The finding of reticulocytosis in alcoholics with fatty liver and hypertriglyceridemia became the triad of Zieve syndrome.[777] The major component of the reticulocytosis represents the return of a marrow formerly suffering the dual effects of alcohol suppression and vitamin deficiencies.

Alcohol and the White Blood Cell

Leukopenia may be caused by an ethanol effect on the marrow independent of any megaloblastic interference with hematopoiesis. Direct marrow suppression of granulopoiesis by alcohol is accompanied by inhibition of release of colony-stimulating factors by T lymphocytes.[778,779] This may contribute to the high morbidity and mortality rates associated with pneumococcal sepsis in the alcoholic with leukopenia.[780]

The alcoholic is further handicapped as an infected host because of diminished adherence, chemotaxis, and motility of granulocytes in response to infection.[781] Macrophage function is impaired with decreased motility and phagocytic performance.[782,783] Immune defenses are also diminished. Both lymphopenia and inhibition of lymphocyte transformation are common in alcoholism.[784] The ability to respond with delayed hypersensitivity to new antigens is also compromised.[785] The mechanism of alcohol-related functional defects of white blood cells is not established, although a raised intracellular concentration of cyclic adenosine monophosphate in the presence of ethanol has been suggested as the cause.[786]

Alcohol and Platelets

Both platelet number and function are adversely affected by alcohol in the absence of any supplementary contribution of vitamin deficiency or hypersplenism. The thrombocytopenia originates in a modest shortening of platelet survival combined with a more significant impairment of megakaryocytopoiesis. In vivo and in vitro experiments confirm that the number and proliferation of megakaryocytes are not altered in the presence of ethanol.[787] The lesion created by the agent appears at the later stages of the megakaryocyte maturation, with inhibition of platelet production. Withdrawal of ethanol is followed within 3 to 5 days by a release of platelets, with levels rebounding to thrombocythemic levels before returning to normal levels in 1 to 3 weeks.[788] Alcohol suppression of thrombopoiesis may be severe enough to result in bleeding, especially when other defects such as gastritis already exist in the patient.

Qualitative platelet abnormalities are also induced by ethanol. With moderate doses (more than 50 g) of ethanol, no direct effect is seen on bleeding time, although this amount of ethanol significantly potentiates prolongation of the bleeding time induced by aspirin and nonsteroidal analgesics. Larger ethanol ingestion results in prolongation of the bleeding time even in the absence of any thrombocytopenia.[789] Defects in platelet aggregation, thromboxane release, and platelet factor 3 availability occur on exposure of platelets to alcohol. These qualitative defects may be secondary to direct toxic effects of ethanol on the platelet membrane in addition to any contribution from an increased plasma osmolality in the presence of ethanol.

Thermal Injury

More than 140 years ago Schultze observed that red blood cells heated to temperatures approaching 50° C for short periods developed membrane budding, fragmentation, and microspherocytosis.[790] This phenomenon was further defined by the careful studies of Ham and colleagues and others and is now believed to be due to heat denaturation of spectrin or other membrane proteins. Similar changes are observed acutely in patients with major cutaneous burns, presumably because of heat exposure of red blood cells in the skin and subcutaneous

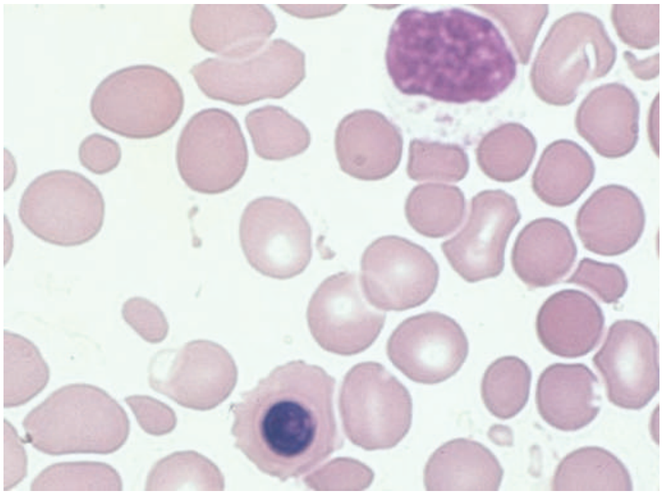

Figure 37-19 Spherocytes, red blood cell fragmentation, and a nucleated red blood cell in a patient with burn-associated hemolysis.

tissues. During the first 24 to 48 hours after the burn, intravascular hemolysis develops, which is associated with red blood cell fragmentation and spherocytosis (Fig. 37-19).[791,792] The severity of the reaction is related to the extent and degree of the burn. Generally, hemolysis is evident in patients with third-degree burns involving 15% to 20% or more of the body surface area.[791,793] In severely burned patients, up to 30% of the red blood cell mass may be destroyed. This acute hemolytic process is usually complete by the third day after the burn and is followed by a chronic anemia resembling that seen in various chronic disorders.[794,795] An unusual variant of this disorder has been reported after infusion of red blood cells that were inadvertently overheated in a blood warmer.[796,797]

Venoms

The venoms of cobras and certain vipers and rattlesnakes may produce severe hemolysis and spherocytosis.[798-802] Spherocytic hemolytic anemia may also be seen in patients bitten by the common brown spiders (*Loxosceles reclusus* and *Loxosceles lata*) of South America and the central and southern sections of the United States[803,804] and in individuals with massive numbers of stings of honeybees, wasps, or yellow jackets.[804-807] Hemolysis in a child stung by a Portuguese man-of-war jellyfish has also been reported.[808] A detailed review of the hematologic manifestations after snake bites can be found in Chapter 38.

A full description of the numerous toxins in these venoms and their mechanisms of action is beyond the scope of this chapter. In general, the mechanisms of hemolysis after envenomation are not fully understood. The venoms of snakes and insects often contain phospholipases (particularly phospholipase A_2) and protein toxins that enhance their action.[809] Examples of toxins include the mastoparans of wasp and hornet venoms and melittin, a polypeptide contained in honeybee *(Apis mellifera)* venom that immobilizes and clusters erythrocyte band 3, producing protein-free areas of the lipid bilayer that are susceptible to phospholipase action.[810-816]

Hemolysis after brown recluse spider bites is characteristically delayed from 1 to 5 days and is caused by a different mechanism.[817] Affected patients develop a transient, spherocytic, hemolytic anemia that produces positive Coombs test results with erythrophagocytosis and IgG and C3 deposition on the red blood cell surface.[818-821] Venom from the brown recluse spider induces activation of an endogenous metalloproteinase, resulting in glycophorin cleavage from the erythrocyte membrane that facilitates the complement-mediated hemolysis.[822-824] The hemolysis usually subsides within a week, but it may be fatal. Complement appears to play a critical role because complement-deficient guinea pigs are resistant to the venom.[825] In vitro models demonstrate that the complement-mediated hemolysis, after exposure to this venom, may be partially inhibited by treatment with complement inhibitor therapy.[825a] The glycoprotein, CD59, may play a previously unrecognized role in membrane protection from venom-induced injury.[826] The venom also contains a phospholipase D that may contribute to the hemolysis.[827]

Except for spider bites, which may be clinically deceptive initially, the potential for a hemolytic catastrophe should be obvious in patients who have been bitten or stung.[817] An early sign of impending hemolysis may be a rapid rise in the serum potassium level caused by the prelytic leak of this ion from the red blood cells. Once hemolysis is established, therapy other than transfusions is usually of little use. In patients with snake bites, localization or drainage of the venom and prompt administration of antivenom can be lifesaving.

CHAPTER 38

Hematologic Manifestations of Systemic Diseases in Children of the Developing World

David J. Weatherall, Dominic P. Kwiatkowski, and **David J. Roberts**

CHAPTER OUTLINE

PREVALENCE AND MULTIPLE CAUSES OF ANEMIA IN THE THIRD WORLD
HEMATOLOGIC CHANGES ASSOCIATED WITH SPECIFIC INFECTIONS IN THE TROPICS
Malaria
Visceral Leishmaniasis (Kala-azar)
Schistosomiasis
Trypanosomiasis
Hookworm
Bartonellosis
Complex Hematology of Childhood Human Immunodeficiency Virus Infection in Developing Countries
TROPICAL EOSINOPHILIA
HEMATOLOGIC ASPECTS OF MALABSORPTION IN THE TROPICS
HEMOSTATIC FAILURE AS A MANIFESTATION OF SYSTEMIC DISEASE IN THE TROPICS
Dengue
Other Viral Hemorrhagic Fevers
Snake Bite
GEOGRAPHIC VARIABILITY IN THE DISTRIBUTION AND EXPRESSION OF HEMATOLOGIC DISEASE
Lymphoma and Leukemia
Hereditary Blood Disorders
Aplastic Anemia
Hematologic Disorders Unique to Certain Countries
ASPECTS OF CLINICAL MANAGEMENT
Treatment of Severe Anemia in the Tropics
Problems with Blood-Borne Infection and Blood Transfusion
Management of Imported Malaria
Leishmaniasis

Diagnosis and management of hematologic disorders in children in developing countries pose a number of problems that are not encountered in advanced Western societies.[1,2] Although all the conditions that have been described in this book are seen in these populations, their clinical features may be modified to a varying degree by the coexistence of malnutrition, chronic bacterial infection, or parasitic illness. Furthermore, many of the common killers, particularly in tropical climates, produce their own complicated hematologic manifestations.

It therefore follows that the study of hematologic disease in these populations presents a particular challenge to hematologists. It is often very difficult to define the clinical and pathophysiologic features of a single hematologic disorder in this setting. Sickle cell anemia is a good example. This disorder, as described in Chapter 19, usually produces a well-defined clinical and hematologic picture in North American or European children. However, the disease may be different in the rural populations of Africa, where its course is generally complicated by diarrheal illness, malnutrition, endemic malaria, and as yet ill-defined climatic effects on the clinical phenotype. It is very difficult to separate the environmental and genetic factors that must underlie the extraordinarily varied severity of this condition in different parts of the world.

The same problems are encountered when attempts are made to define the hematologic manifestations of disorders that are peculiar to tropical climates. For example, despite many years of intensive investigation, it is still not possible to provide a clear picture of the pathophysiologic cause of the anemia of malaria caused by *Plasmodium falciparum* infection. Although investigators have been unable to provide a clear picture for many reasons, the major difficulty for persons who wish to study this important problem is finding patients with malaria who do not have other diseases that may cloud the clinical picture, such as chronic bacterial infection, human immunodeficiency virus (HIV) infection, malnutrition, hemoglobinopathies, or red blood cell glucose-6-phosphate dehydrogenase (G6PD) deficiency (see Chapter 17).

Despite these difficulties, in recent years it has been possible to start to understand the pathogenesis of some of the hematologic manifestations of systemic disease in children in the Third World. In this chapter some of the progress that has been made in this extremely important area of childhood hematology is reviewed.

PREVALENCE AND MULTIPLE CAUSES OF ANEMIA IN THE THIRD WORLD

Numerous surveys have been conducted to determine the prevalence of anemia in tropical populations.[3-6] However, because of differences in methodology and demographic design, it is very difficult to interpret the results and compare one study with another. Representative data from several countries, using the World Health Organization definition of anemia (Table 38-1),[7] are shown in Table 38-2. It is clear that in many populations the prevalence of anemia in preschool children is extremely high, and in some locations almost 100% of the population is affected. Although the data shown in Table 38-2 were compiled more than 20 years ago, the situation remains serious. Although the 2010 Global Burden of Disease study investigators described a modest decrease in the global prevalence rates of anemia, they also reported that the burden of anemia, as measured in years lived with disability (YLDs), had increased from 65.8 to 68.3 million YLDs, or 8.8% of the global total of YLDs from all conditions.[8]

It is equally difficult to determine the relative importance of different causes of anemia in the tropics. Most surveys have concentrated on only one mechanism, such as iron or folate deficiency. However, to get a true picture of the cause of anemia in a particular population, it is necessary to obtain consecutive data over a substantial period. For example, studies in Gambia have shown that mean hemoglobin levels in children vary significantly at different times of the year; anemia is much more common in the wet season when malaria transmission is at its highest (Fig. 38-1).[5] The wet season is also the time when diarrhea and malnutrition are most common because heavy rains after many dry months have profound effects on the community, sanitation measures are disrupted, and food stores are at a low point in the annual cycle. Although these observations emphasize the multifactorial cause of anemia, it is clear that iron deficiency, which affects at least 20% of the world's population, is the major factor and that the numerous other diseases that may exacerbate anemia are often operating in the setting of low stores of iron in the body.

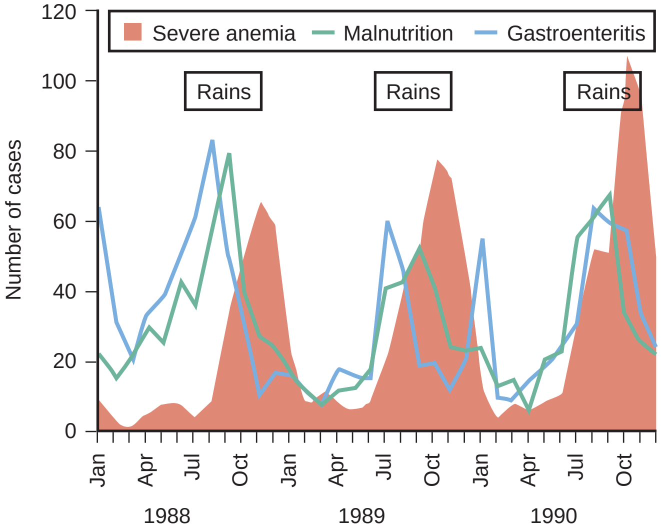

Figure 38-1 Admissions to the children's ward of a hospital in Gambia, where malaria transmission is confined to the rainy season. The incidence of severe malarial anemia corresponds to seasonal epidemics of malaria fever and cerebral malaria. Gastroenteritis and malnutrition also reach a peak incidence in the early part of the rainy season and thus contribute to the multifactorial cause of the anemia. *(Data from Brewster DR, Greenwood BM: Seasonal variation of paediatric diseases in The Gambia, West Africa.* Ann Trop Paediatr *13:133–146, 1993.)*

The body's response to infection may also reduce iron stores and iron utilization. The level of hepcidin, the body's main regulator of iron absorption,[9] is modified by proinflammatory mediators such as tumor necrosis factor

TABLE 38-1 World Health Organization Criteria for Hemoglobin Concentrations below Which Anemia Is Considered to Be Present in Populations at Sea Level

Age	Hemoglobin Concentration (g/dL)
Children, 6 mo–6 yr	11
Children, 6-14 yr	12
Adult males	13
Adult females (nonpregnant)	12
Adult females (pregnant)	11

(TNF) and interleukin (IL)-6, which are elevated in a wide variety of infections. High hepcidin levels stimulated by malaria infection or bacterial infections reduce absorption of iron from the gut and also reduce incorporation of iron into red blood cells. Iron may act as a growth factor for malaria parasites, and thus a raised hepcidin level and a reduction in available iron may form part of a protective innate response to malaria infection. However, this protective response may contribute to functional iron deficiency and anemia in endemic areas.

Iron deficiency and anemia are less common in groups that have persisted as hunter-gatherers, such as the Hadza in Tanzania and the pastoralists who drink blood and eat meat—for example, the Masai in Kenya.[2] On the other hand, absorption of nonheme iron, except from breastmilk, is comparatively restricted, and the content of iron in breastmilk is very low. Therefore iron deficiency is common in communities whose food is predominantly of vegetable origin.[10] The three great staples in these populations are rice, wheat, and maize. Sorghum and millet are also important in some areas of Africa and Asia. Soy and similar legumes are major sources of protein in many countries. The iron content of these diets is generally low and absorption is inhibited by fiber, phytates, phosphates, and polyphenols, which are all found at high levels in these largely vegetarian diets.[10] Loss of iron from chronic hemorrhage resulting from hookworm infection or schistosomiasis further contributes to the high incidence of iron deficiency anemia in the developing world.

The infants of mothers with iron deficiency have low iron stores, their folate status at birth reflects that of their mother, and the folate content of breastmilk is diminished by maternal deficiency and maternal malaria.[11-13]

In many populations, anemia may be associated with folate deficiency.[3,4,13] Again, the reasons for the deficiency are complex and multifactorial. Although intake of folate varies widely among different populations, depending on the way in which food is prepared and the temperature at which it is cooked, it is clear that low intake is not necessarily the result of lack of folate in the diet. Work in Africa suggests that the continuous anorexia associated with recurrent infections such as malaria or tuberculosis is the most important cause of folate deficiency in children.[2] As will be discussed later, postinfective malabsorption is a particularly common cause of folate deficiency, especially in the Indian subcontinent. Folate deficiency may be exacerbated by erythroid hyperplasia associated with chronic malarial infection or hemoglobinopathy.[14]

Although nutritional vitamin B_{12} deficiency is uncommon, Indian infants born to mothers with sprue (discussed later) who are fed breastmilk or goat milk containing insufficient vitamin B_{12} may be susceptible to megaloblastic anemia with locomotor complications during the early months of life.[2] This syndrome, which is often fatal, appears to be complicated by a marked predisposition to infection.

Although many of the population surveys on the prevalence of anemia in tropical countries have concentrated on one particular cause and intercurrent illness has not been assessed, studies in Africa—in which attempts have been made to assess body iron stores, folate levels, and the presence of intercurrent infection—indicate that chronic recurrent malaria, without other important complicating factors, is the major cause of anemia in these populations.

A major issue is whether iron supplementation is the most effective way to prevent anemia in regions where malaria is highly endemic. For example, a study in Tanzania showed that either iron supplementation or malaria chemoprophylaxis could be used to reduce the incidence of anemia in the first year of life but that the benefits of malaria prophylaxis were outweighed by increased risk for both malaria and anemia after the prophylaxis was stopped, thus suggesting that iron supplementation is the better option.[15] Then again, a reduction in iron levels is part of the natural host defense against infection, and a long-standing debate has ensued about whether supplementation has adverse consequences, particularly on mortality from infectious diseases.

Studies with a large sample size are needed to address this issue, and results of two such studies have recently been published. On Pemba Island, Zanzibar, where malaria is endemic, an initial study found that iron supplementation improved motor and language development,[16] but a subsequent larger study involving 24,000 children found that deaths and hospital admissions were significantly higher in children who received iron and folate supplementation compared with children who did not receive such supplementation.[17] Although the cause of increased deaths in the children receiving supplementation was not precisely defined, malaria appeared to play a major role. In contrast, authors of a study of 25,000 preschool children in southern Nepal found that children who received iron and folic acid had no significant difference in mortality compared with children who did not receive the supplements, although modest protective effects against diarrhea, dysentery, and acute respiratory illness were suggested.[18]

Iannotti and colleagues[19] reviewed 26 randomized controlled trials of preventive oral iron supplementation in children younger than 5 years. Their general conclusion was that iron-deficient children may need to be identified to ensure that iron supplementation programs are effectively targeted to improve hemoglobin levels and cognitive and motor development. Although no effect on morbidity was found in most studies, few had an adequate sample size or study design to resolve this issue. The outcome of a supplementation program may depend greatly on the pattern of endemic disease in the population.

HEMATOLOGIC CHANGES ASSOCIATED WITH SPECIFIC INFECTIONS IN THE TROPICS

Malaria

Malaria is the most important parasitic illness that affects humans.[20] The total burden of disease has recently been estimated to be 515 million episodes annually, and malaria is responsible for 18% of all childhood deaths in sub-Saharan Africa (equivalent to 800,000 deaths each year).[21,22] With increasing drug resistance of the malarial parasite, the problems of both treatment and control are becoming more complex, and this disease remains one of the major unsolved world health problems, although the widespread use of insecticide and bed nets appears to be reducing the incidence of severe malaria in many parts of Africa.

Life Cycle and Species

Because of its peculiar life cycle (Fig. 38-2), the malarial parasite is particularly prone to cause hematologic manifestations. During a blood meal, female anopheline mosquitos inject sporozoites that disappear from the circulation after about 1 hour and enter liver parenchymal cells, where they proliferate into thousands of merozoites (Fig. 38-3). The period of development in liver cells varies between species. Merozoites rupture from liver cells, pour into the bloodstream, and invade erythrocytes. Further development of the intraerythrocytic parasite follows one of two pathways: asexual differentiation or differentiation into sexual parasites called gametocytes (Fig. 38-4). The latter continue their development within anopheline mosquitos. Asexual parasites develop from young ring forms through trophozoites to dividing forms called schizonts (Fig. 38-5). Upon rupture of infected erythrocytes, forms called merozoites are released, invade other erythrocytes, and thus continue the erythrocyte cycle. When billions of schizonts rupture simultaneously and release cytokine-inducing toxins, they cause paroxysms of malarial fever.

When a child is infected with malaria for the first time, the result is usually an intermittent febrile illness lasting a few weeks, but complete eradication of malarial parasites from the bloodstream may take months or years. In the phase between cessation of the fever and final resolution of the infection, the child may appear well, but the destruction of red blood cells continues. From a hematologic viewpoint, the major question is how soon will the child be reinfected, because in some communities reinfection occurs almost every day, and immunity to malaria is slowly acquired and never complete. In regions of high transmission, children eventually acquire the ability to maintain a parasite density below the level that causes fever, but chronic or repeated infections cause a state of chronic anemia.

Four species of *Plasmodium* infect humans—*P. falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*—and a fifth species, *P. knowlesi*, which is normally restricted to macaque monkeys, has recently been discovered in the human population in Borneo.[23] Each has particular morphologic and biologic properties and clinical manifestations. *P. falciparum* is the predominant cause of clinical malaria in Africa and much of Southeast Asia, whereas *P. vivax* tends to predominate in Central America and the Indian subcontinent, but their distribution overlaps considerably and multiple infections are not uncommon. *P. vivax* is essentially absent in populations of Central and West Africa because their erythrocytes fail to express the Duffy antigen or IL-8 receptor, to which the merozoites of this species attach during invasion.[24,25]

Another peculiarity of *P. vivax*, also shared with *P. ovale*, is the ability to form hypnozoites, which can

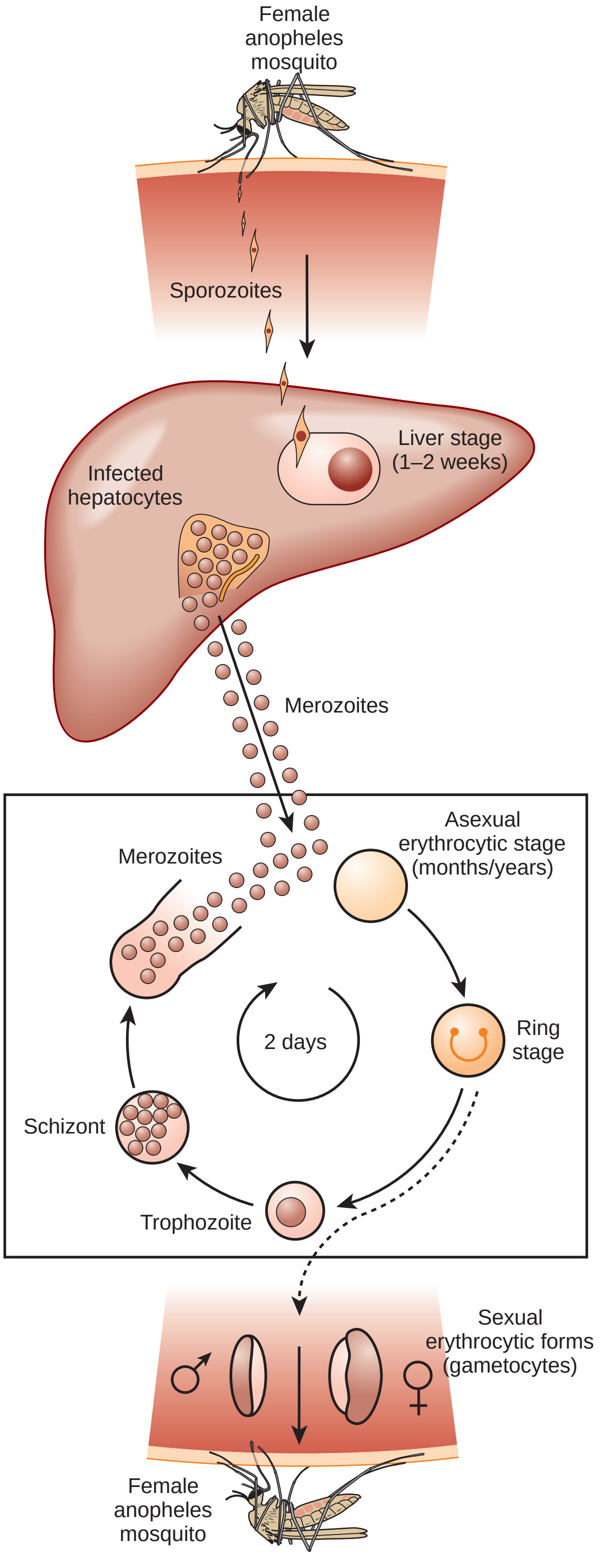

Figure 38-2 The life cycle of malarial parasites. The duration of the erythrocyte cycle is 48 hours for all human malaria parasites except *Plasmodium malariae*, which has a 72-hour cycle.

remain dormant in cells for months or years. This ability results in relapsing infections that are often associated with mild chronic anemia. However, profound anemia and other grave complications are almost always seen with *P. falciparum* malaria, and the following sections apply mainly to this particular species.

Severe Malaria

Life-threatening complications are estimated to occur in about 1% of episodes of *P. falciparum* infection in African children, and it has been estimated that a child in rural Africa has a 15% lifetime risk of a malaria infection that requires hospital admission as a result of complications.[26] Such complications include profound anemia, cerebral malaria (a syndrome of unarousable coma that is often accompanied by severe convulsions), hypoglycemia, jaundice, renal failure, pulmonary edema, and coagulation abnormalities. Important and as yet largely unexplained differences are seen in the clinical spectrum of severe *P. falciparum* malaria in different parts of the world.[27] In Southeast Asia, all the aforementioned complications are commonly seen, whereas in Africa, where cerebral malaria and severe malarial anemia together account for about 1 million deaths per year and hypoglycemia is also common, the other complications of *P. falciparum* malaria are surprisingly rare. Malarial illness affects mostly children in Africa, whereas adults are more commonly affected in some other parts of the world; it has been suggested that much of the variation in clinical symptomatology is related to age. However, this theory does not provide a full explanation. Even among African children regional differences exist, and the impression is growing that higher rates of malarial transmission lead to a greater prevalence of anemia but, paradoxically, a low incidence of cerebral malaria.[28]

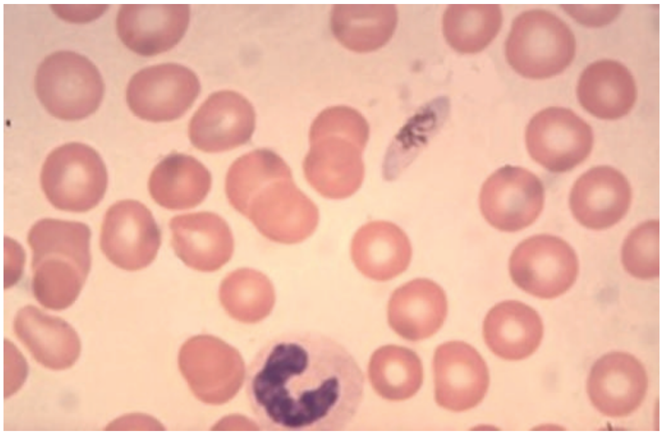

Figure 38-4 A *Plasmodium falciparum* malarial gametocyte in the blood.

The lethality of *P. falciparum* compared with other species of *Plasmodium* probably stems from two biologic properties. First, the parasite density that it achieves is typically a hundred times higher than that of other species before its growth is curtailed by host defense mechanisms.[29] Second, mature intraerythrocytic forms of *P. falciparum* adhere to the endothelium of postcapillary venules and thus sequester in tissues. Because these properties are common to all strains of *P. falciparum*, the greater puzzle is why lethal complications arise in only a minority of infected persons. Some important clues have emerged recently. Parasite sequestration is mediated by a parasite-derived molecule known as PfEMP1 that is expressed on the surface of a mature infected erythrocyte and binds to a variety of endothelial adhesion molecules, including CD36, intracellular adhesion molecule 1, E-selectin, and vascular cell adhesion molecule.[30] Whether a parasite will bind to a specific endothelial adhesion molecule is determined by its PfEMP1 type, which shows an extraordinary degree of phenotypic variability.[31] Expression of endothelial adhesion molecules varies between organs and is regulated by cytokines released by the host in response to the infection, such as TNF.[32] Another potentially important pathophysiologic mechanism is vascular sludging, which results from the clumping of parasitized erythrocytes, either with platelets ("autoagglutination" or "clumps") or with unparasitized erythrocytes ("rosettes"). Both phenomena are strain specific and have been associated with the severity of malaria.

As usual, the parasite uses diverse adhesive mechanisms; complement receptor–1 is a key binding target for some rosetting parasites,[33] whereas the platelet glycoprotein CD36 and other as yet unknown proteins are used in the formation of autoagglutinates or clumps.[34] Rosetting has been found to be reduced in persons with blood group O[35] who are known to be protected against severe malaria.[36]

Recognition is growing that a significant proportion of cases of severe malaria in the tropics are bacteremic.[37] Sickle cell trait has been found to be protective against bacteremia, which has led to the discovery—using an epidemiologic method known as mendelian randomization—that *P. falciparum* infection is a strong predisposing factor for bacteremia in Kenyan children.[38] An interesting relationship exists between salmonellosis, malaria, and malarial anemia.[39,40] It remains open to speculation whether *Salmonella* infection aggravates malarial anemia, whether anemia is a marker of chronic malarial infections that favor salmonellosis, or whether some other explanation exists for this curious and striking relationship.[41]

Malarial Anemia

The pattern of hematologic changes in malaria varies considerably, depending on the type of patient. During an acute attack of *P. falciparum* malaria in a nonimmune person, the hematocrit starts to decrease after 1 or 2 days and continues to decrease for about 1 week after antimalarial treatment.[42,43] Subsequently, a steady increase in the hematocrit usually occurs, although several weeks may pass before the hematologic picture is back to normal. The anemia, which is not usually life threatening, is characterized by both hemolysis and an ineffective marrow response,[42,43] features that have also been documented in persons with acute *P. vivax* infection. When profound anemia occurs with acute *P. falciparum* malaria, it is often associated with multiorgan failure, although it can also occur as an isolated complication.

From the perspective of the health of children who live in the tropics, the most important hematologic problem is seen in a child chronically infected with *P. falciparum*, whose anemia is debilitating and sometimes fatal. Although this problem most commonly occurs in areas of high malarial transmission, it is a growing problem in regions of lower transmission because of the increase in resistance to antimalarial drugs, which has served to prolong the average duration of infection. Attempts to investigate the problem of chronic malarial anemia are often hampered by the coexistence of iron or folate deficiency and hemoglobinopathies. In a study in which patients with these conditions were carefully excluded, the most striking pathophysiologic findings were hemolysis, hypersplenism, and a suboptimal bone marrow response.[43] In the sections that follow, some of the mechanisms for these components of the anemia of malaria are discussed in more detail.

Role of Hemolysis. Normal children living in rural Africa typically have extremely low levels of haptoglobin that increase significantly after institution of malaria prevention programs,[43,44] thus providing some indication of the burden of chronic hemolysis that malaria causes in many tropical communities. The mechanisms of red blood cell destruction in persons with *P. falciparum* malaria are complex and not fully understood.[45] Clearly, erythrocytes are destroyed when schizonts rupture and release their progeny, and depending on the state of immunity, a proportion of the parasitized erythrocytes are destroyed by the host before schizont rupture can take place. Both mechanisms can have devastating consequences if the patient is hyperparasitemic (sometimes more than 50% of erythrocytes are infected), but such patients are rare. In most infections, fewer than 1% of erythrocytes are infected, a loss that is important in the context of chronic infection but would not account for the severity of anemia that is commonly observed. Both mathematical modeling and clinical observation suggest that 10 times as many uninfected erythrocytes are removed from the circulation for each infected erythrocyte.[46] Indeed, cross-transfusion experiments clearly indicate that erythrocyte survival is shortened both in the acute phase of malaria and during convalescence.[47,48]

Role of the Spleen. Some degree of splenomegaly is a normal feature of malarial infection, and the prevalence of splenomegaly in regions of malarial transmission is used as a major indicator of the level of malarial endemicity. The importance of the spleen in host defense against malaria has been demonstrated in experimental systems, and persons whose spleens have been surgically removed are thought to be more susceptible to severe infection (discussed later). The phenomenon of parasitic sequestration, discussed earlier, is thought to have evolved primarily as an immune evasion strategy whereby the mature parasite can avoid passing through the spleen.[49]

Several studies have attempted to define the pathophysiologic changes that occur in the spleen during the acute phase of malaria. In animal models, malaria is accompanied by increased intravascular clearance of infected or rigid heat-treated cells by the spleen,[50] alterations in the splenic microcirculation,[51] and recruitment of myelomonocytes to the spleen and liver.[52] In studies of human malaria it has been found that increased splenic clearance of heated red blood cells occurs during acute attacks.[53] Reduced deformability of uninfected red blood cells is observed in *P. falciparum* malaria and is a significant predictor of the severity of anemia, consistent with the notion that these cells are being removed by the spleen[54] (discussed later). It has also been found that immunoglobulin G (IgG)-sensitized red blood cells are rapidly removed from the circulation by the spleen and that unusually rapid clearance persists well into the convalescent phase.[55] Undoubtedly, the activity and number of macrophages are increased during human malarial infection, which may therefore contribute to the increased removal of uninfected cells.[56-58]

In rodent malaria, a model of chronic anemia has been developed in which *Plasmodium berghei*–infected semi-immune mice show a fivefold to tenfold increase in the clearance of uninfected erythrocytes, although the extent of parasitemia remains below 1%.[59] In this study, clearance of uninfected red blood cells was delayed in mice depleted of macrophages, thus supporting the view that removal of uninfected erythrocytes is an important factor in persons with anemia.

All the available evidence therefore points to increased reticuloendothelial clearance in *P. falciparum* malaria that persists long after recovery. These changes are presumably a host defense mechanism to maximize the clearance of parasitized erythrocytes. Clinical studies have also uncovered a curious phenomenon whereby some erythrocytes appear to be returned to the circulation after having had their parasites removed,[60] but killing parasites usually means destroying erythrocytes, and it appears that the survival of uninfected red blood cells is reduced in the process.

These observations in patients are consistent with findings at the cellular level. Active erythrophagocytosis is a conspicuous feature within the bone marrow of persons with *P. vivax* and *P. falciparum* malaria,[61,62] and it is highly probable that it also occurs within the spleen. Children with acute *P. falciparum* malaria have high circulating levels of interferon-γ and TNF,[63] a synergistic combination of cytokines that activate macrophages.[64] Transgenic mice that constitutively overexpress human TNF are anemic and show enhanced clearance of autologous erythrocytes, which is presumed (though not proved) to be due to erythrophagocytosis.[65] When infected with *Plasmodium yoelii* or *P. berghei*, transgenic mice suppress parasite density much more effectively than their littermates do. This finding supports the notion that with relatively nonspecific effector mechanisms such as erythrophagocytosis within the spleen, anemia is part of the price that the host has to pay for protection against overwhelming parasitemia.

Massive Intravascular Hemolysis. A peculiar example of malaria-associated hemolysis is blackwater fever.[45,66] The classic form of this syndrome, often reported in colonial times among Europeans living in Africa, was characterized by fever and massive intravascular hemolysis associated with low or no parasitemia; it led to renal failure and was associated with high mortality. It was suspected that intermittent quinine ingestion might have led to a drug-induced immune hemolysis, although this mechanism was never proved and recent reports have implicated newer antimalarial drugs such as halofantrine and mefloquine/artemisinin combinations.[67,68] Classic blackwater fever is now much less common, but it is important to remember that massive intravascular hemolysis with hemoglobinuria remains an important complication of *P. falciparum* malaria in Southeast Asia in both children and adults.[42] Blackwater fever is sometimes associated with high parasitemia or destruction of G6PD-deficient red blood cells by oxidant antimalarial drugs. A survey of cases in Vietnam found considerable overlap of quinine ingestion, G6PD deficiency, and concurrent malaria, suggesting that these different factors may interact, but they certainly do not all have to be present for blackwater fever to occur.[69] It is conceivable that hemolysis is caused by the rupture of a large number of sequestered parasites, but the possibility of another hemolytic process has yet to be ruled out.

Decreased Erythrocyte Deformability. The increased clearance of uninfected erythrocytes is due not only to the activation of splenic macrophages but also to extrinsic and intrinsic factors that enhance their recognition and phagocytosis. Uninfected erythrocytes have reduced deformability, which leads to enhanced clearance in the spleen. The mechanism responsible for the loss of deformability is not completely understood, however. Increased oxidation of membranes in uninfected erythrocytes has been demonstrated in children with severe *P. falciparum* malaria, and the ongoing inflammatory insults associated with acute malaria (proinflammatory cytokines) or the direct effects of parasite products have been shown to cause loss of red blood cell deformability.[57,70,71] Intriguingly, a severe reduction in red blood cell deformability measured on admission is also a strong predictor not just for anemia but also for mortality, both in adults and children with severe malaria.[54,72]

Immune Complex–Mediated Hemolysis. It is also possible that at least part of the hemolysis in *P. falciparum* malaria might have an immune basis. A positive direct Coombs antiglobulin test (DAT) is seen in some patients with malaria.[43,73-79] As with all studies of malaria, considerable differences in the incidence of positive DAT results in malarial infection seem to exist in different populations and at different ages. For example, in Thai children or adults during their first attack or with subsequent attacks in persons who live in areas where a degree of immunity has not developed, DAT results are invariably negative.[78] Furthermore, studies using labeled immunoglobulin have shown that the number of antibodies bound to the red blood cells of patients with malaria of this type is no different from that in uninfected control subjects of the same age and in the same location.[78]

The position is different in African children who have experienced repeated attacks of malaria. Positive DAT results have been found in up to 50% of these children, and the incidence is significantly higher in children with active malarial infection than in those who are not infected.[74-77,79] The phenomenon is age related and is more common in young children. DAT results may remain positive for several weeks after an acute infection. Use of specific antisera has revealed that the most common type of red blood cell sensitization occurs with C3; other specificities include IgG alone, IgG plus C3, IgG plus C3 and C4, and various other combinations of IgG with complement components.[74-78] The IgG that can be eluted from these cells has specific activity against *P. falciparum* schizont antigen,[74] which suggests that the erythrocyte coating results from passive attachment of circulating complement-fixing malarial antigen-antibody complexes. It is therefore likely that the development of positive DAT results is part of the immune response to *P. falciparum*.

Other studies have suggested that the *P. falciparum* ring surface protein 2 (RSP-2) may be one component of the immunoglobulin-antigen complexes deposited on uninfected erythrocytes. This protein is expressed on infected erythrocytes shortly after merozoite invasion and may mediate some adhesion of infected erythrocytes to endothelial cells. RSP-2 is also deposited on uninfected

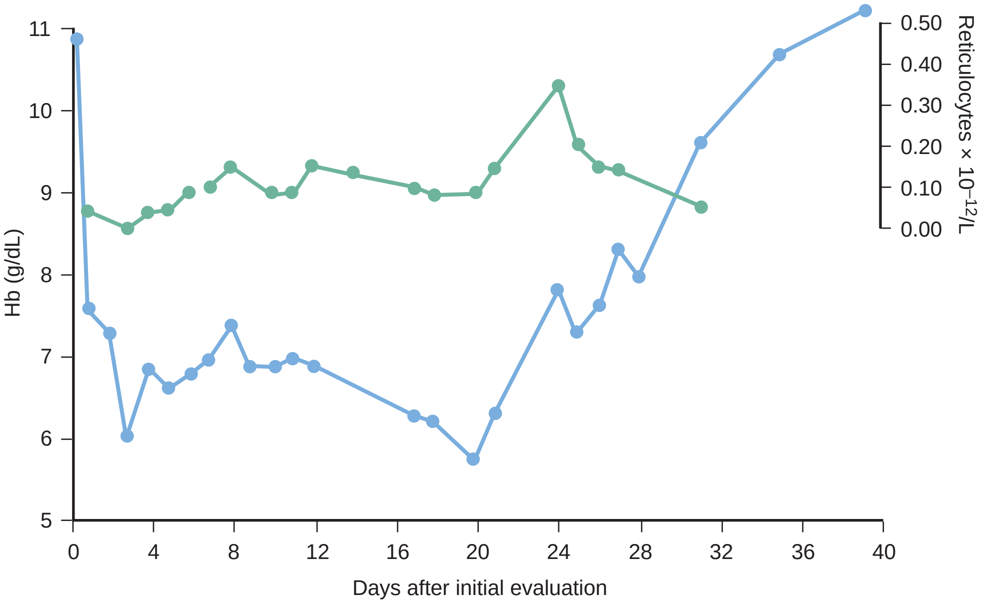

Figure 38-6 Hemoglobin (Hb) level and reticulocyte response in a nonimmune patient with *Plasmodium falciparum* malaria.

erythrocytes and forms immune complexes that contribute to the phagocytosis of uninfected erythrocytes. Limited clinical studies have shown that high levels of anti–RSP-2 antibodies are found in the sera of immune adults and children with severe anemia.[80] This antigen is also present on the surface of erythroblasts in the bone marrow of patients infected with *P. falciparum*, thus indicating that clearance or damage to developing erythroid cells by RSP-2 and anti–RSP-2 could contribute to the development of anemia.

However, it is far from clear whether the presence of positive DAT results indicates that immune destruction of red blood cells occurs in African children with malaria. Several studies have shown that no correlation exists between the degree of anemia and positive DAT results,[78,79] and other measured parameters of hemolysis have not correlated with coating of red blood cells. Nonetheless, immune destruction may occasionally be of importance. A small number of patients with severe anemia and positive DAT results have been described who had active C3 components on their red blood cells.[75] In these patients, striking monocyte erythrophagocytosis of nonparasitized erythrocytes was seen.

In some patients with *P. falciparum* infection, IgM antibodies have been reported to develop against triosephosphate isomerase, and disappearance of the antibodies coincides with disappearance of the hemolysis. Because these antibodies can induce erythrocyte lysis and complement activation in vitro, it has been postulated that they may contribute to a hemolytic process in vivo.[81]

In short, little evidence exists for immune destruction of red blood cells in *P. falciparum* malarial infections in nonimmune adults. Although a varying proportion of children with chronic malaria in Africa have positive DAT results, only occasionally is evidence of genuine immune destruction of red blood cells seen. Of course, it is possible that a sensitized red blood cell population is very rapidly destroyed and that subsequent serologic studies have missed this event. However, the persistence of shortened red blood cell survival of nonparasitized cells in the absence of any consistent serologic abnormalities suggests that another factor must be involved in the shortened red blood cell survival in persons with malaria. This factor appears to be nonspecific “overactivity” of the monocyte/macrophage populations of the spleen and liver, as previously discussed.

Defective Marrow Response. In addition to the hemolytic components of the anemia of *P. falciparum* malaria, an inappropriate marrow response undoubtedly occurs.[42,43,45,82,83] For many years it has been noted that the reticulocytosis in response to the decrease in hematocrit is often inappropriately low and delayed (Fig. 38-6). It remains unclear whether defective erythropoietin production is a significant cause, with some studies suggesting an appropriate rise[84] or even enhanced response[83] and other investigators observing a blunted response,[85,86] but there is no question that significant dysfunction of marrow takes place and appears to have a complex multifactorial basis.

It is now clear that disturbances in iron metabolism are mediated by hepcidin.[9] Hepcidin is regulated by proinflammatory mediators such as TNF and IL-6, which are elevated in both murine infections and in patients presenting with severe falciparum malaria, although other parasite-derived and host factors may be involved in stimulating hepcidin production. Hepcidin levels decrease in the most severely ill children because hypoxia inhibits hepcidin production.[87] High hepcidin levels stimulated by blood stage malaria infection are associated with inhibition of liver stage malaria infection in mice[88] and reduced incorporation of iron into red blood cells in humans.[89] Evidence from murine malaria suggests that a low level of serum iron caused by an elevated level of hepcidin

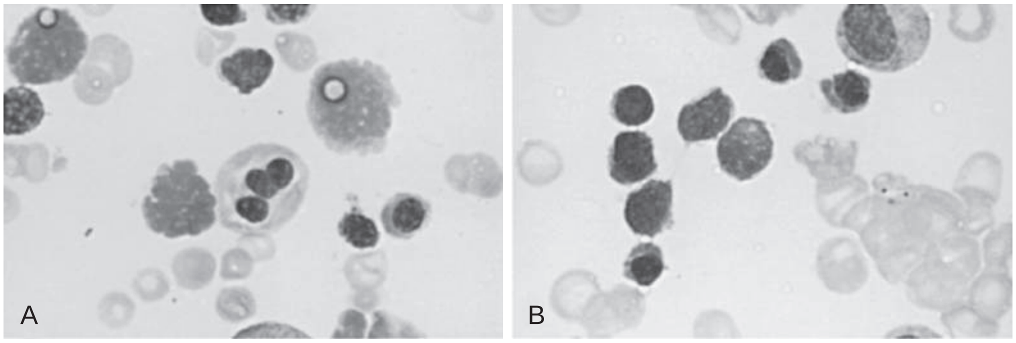

Figure 38-7 Bone marrow from a person with *Plasmodium falciparum* malaria. **A**, Multinucleate red blood cell precursors. **B**, Intercytoplasmic bridging (Leishman stain, magnification ×500).

reduces parasite growth and progression to severe disease.[90] These experimental and clinical findings are consistent with a role for iron as a growth factor for malaria parasites, as well as a role for an increased level of hepcidin and a reduction in available iron as a protective innate response to malaria infection.

Some of the features of iron metabolism and bone marrow structure and function in persons with acute malaria resemble those of other acute infections; thus the serum iron level rapidly decreases and iron appears to be sequestrated into the storage compartments of the marrow.[42,43] Serum ferritin levels are extremely high during the acute phase, although studies of isoferritins suggest a complex source. In many instances it appears that much of the ferritin is released as a consequence of liver damage.[42]

During acute malarial infections, marked dyserythropoietic changes in the bone marrow may occur.[42,43] Although changes are most marked in African children with chronic relapsing malaria,[43] they have also been observed in nonimmune Thai people[42] and in travelers returning to the United Kingdom.[45] These morphologic abnormalities, which have been studied by both light and electron microscopy, consist of erythroblast multinuclearity, karyorrhexis, incomplete and unequal amitotic nuclear divisions, and cytoplasmic bridging (Fig. 38-7).[43] Upon electron microscopic examination, binucleate or multinucleate erythroblasts, bizarre myelination with loss of parts of the nuclear membrane, and widening of the space between the two layers of the nuclear membrane have been observed.[43,62] Some degree of iron loading of the mitochondria and a reduction in electron density of the cytoplasmic matrix appear to occur, together with a paucity of ribosomes. In addition, widespread sequestration of erythrocytes in the sinuses of the bone marrow occurs in persons with an acute infection.[62]

With use of [^{3}H]thymidine autoradiography and Feulgen microspectrophotometry, it is clear that a significant abnormality of red blood cell proliferation in the bone marrow occurs in persons with acute malaria. Changes include an increased proportion of red blood cell precursors in the G_2 phase and arrest in progress of cells in the S phase. These findings are nonspecific and have been observed in other conditions associated with ineffective erythropoiesis.[82]

In addition to these dyserythropoietic changes, erythrophagocytosis is particularly common in the bone marrow in persons with *P. falciparum* malaria.[43] This phenomenon is not restricted to the marrow and may be seen in the spleen and other organs and, as mentioned earlier, may play a role in the hemolytic component of the disease.

Although the mechanism of these dyserythropoietic changes is unknown, it is possible that they are an exaggerated example of the bone marrow suppression that occurs in other situations of chronic infection. An important factor may be the high levels of TNF production that occur during malarial infection because this cytokine has been strongly implicated in the anemia of chronic infection and severe malarial anemia has been associated with certain TNF promoter polymorphisms.[91] TNF suppresses the proliferation of erythroid progenitor cells in human marrow culture, although the effect declines as the cells differentiate.[92] On the other hand, TNF stimulates fibroblasts to secrete growth factors for colony-forming unit–granulocyte-erythrocyte-monocyte-macrophage and burst-forming unit–erythrocyte.[93] In nude mice implanted with transfected Chinese hamster ovary cells that can constitutively express the human TNF gene, erythropoiesis is preferentially suppressed, with a marked reduction of colony-forming unit–erythrocyte and burst-forming unit–erythrocyte in the marrow and spleen.[94] Chronic malaria has specific features that might augment these effects because huge numbers of pigment particles are ingested by the resident macrophages of the spleen and marrow, thereby providing a sustained stimulus for TNF production at the site of erythropoiesis.[95] Furthermore, experimental findings in mice are consistent with a role for TNF in the dyserythropoietic changes of malaria.[96]

Other cytokines have also been implicated. IL-10 is an antiinflammatory cytokine that inhibits TNF, and two clinical studies in African children with severe malarial anemia have found a low ratio of IL-10 to TNF in plasma, thus leading the investigators to propose that defective IL-10 production may pave the way to marrow suppression by TNF.[97,98] IL-12 protects against severe anemia in experimental murine malaria,[99] which might reflect both its antiparasitic actions and effects on erythropoiesis.[100]

Several studies have suggested that a parasite byproduct of hemoglobin digestion, hemozoin, may have an indirect or direct role in impaired erythroid development.[83] Hemozoin stimulates the secretion of biologically active endoperoxides from monocytes, such as 15(*S*)-hydroxyeicosatetraenoic acid and hydroxynonenal, via oxidation of membrane lipids,[101,102] which may affect erythroid growth.[103]

Hemozoin and TNF-α also have additive effects on erythropoiesis in vitro, and in a clinical study, hemozoin-containing macrophages and plasma hemozoin were associated with anemia and reticulocyte suppression.[83] Moreover, bone marrow sections from children who died with severe malaria show a significant association between the quantity of hemozoin (located in erythroid precursors and macrophages) and the proportion of erythroid cells that were abnormal. These findings are consistent with a direct inhibitory effect of hemozoin on erythropoiesis.

Coagulation Abnormalities

Modest thrombocytopenia is not uncommon during acute *P. falciparum* attacks, and, occasionally, the platelet count decreases to as low as 10,000 to 20,000/mL.[42] The mechanisms have not been determined but probably involve platelet activation and adhesion of infected erythrocytes to platelets, and experimental studies in mice suggest that platelets sequester in venules during malarial infection.[104] Adherence of platelets to epithelium appears to be mediated through a specific receptor-ligand interaction involving lymphocyte function antigen–1. Evidence indicating reduced thrombopoiesis during acute infection also exists.

In some patients with severe *P. falciparum* malaria, a severe bleeding diathesis may develop during the acute phase of the illness. Although it has been suggested that the diathesis results from disseminated intravascular coagulation, studies in Thailand have not substantiated this supposition.[42] Rather, the bleeding appears to reflect gross thrombocytopenia together with liver damage. However, it is becoming apparent that approximately 10% of African children with severe malaria also have bacteremia,[39] and thus when disseminated intravascular coagulation occurs, the cause may be complex.

Malaria in Pregnancy

In endemic regions, it is extremely common for women to have malaria while they are pregnant. The placenta provides a favorable environment for parasite replication, and specific pathways of adhesion of infected erythrocytes to the surface of syncytiotrophoblasts have now been unraveled. A specific variant antigen, PfEMP1, which is expressed on the surface of infected erythrocytes (varCSA-2), mediates adhesion of infected erythrocytes to chondroitin sulfate. Primigravidae are particularly susceptible to malarial infection and may become systemically unwell, but immunity to this variant antigen modulates the duration and severity of infection in subsequent pregnancies. These observations suggest that varCSA-2 may be an excellent candidate antigen for a pregnancy-specific malaria vaccine. Apart from the effects on the mother, malaria is an important cause of low birth weight and increased perinatal mortality. Studies of cord hemoglobin levels indicate that it is also a significant cause of fetal anemia. Because the severity of the fetal anemia is out of proportion to the degree of maternal anemia, it has been suggested that intrauterine hemolysis may be involved.[105] Malaria during pregnancy is a preventable illness, although it has become more difficult to control with the rise of resistance to antimalarial drugs. Studies in different parts of Africa have found placental malaria to be an important risk factor for anemia in the first 6 months of life.[106,107]

Given the high prevalence of malaria in pregnancy and the strong association of placental malaria with infantile anemia, it is surprising how few infants have overt symptoms of congenital malaria in the tropics. On the rare occasions when it does occur, it can result in a perplexing hematologic disorder. The manifestations of malaria may not be seen until several months after birth, presumably because of passive immunization from the mother and possibly the fact that *P. falciparum* tends to grow less effectively in cells that contain relatively large amounts of fetal hemoglobin. The disease is characterized by a febrile illness associated with anemia that may often be profound.[105] As in conventionally acquired malaria, the pathophysiologic course of the anemia is a complex combination of hemolysis and marrow suppression. Thus it is important to obtain a careful travel history from the parents of any infant with unexplained hemolysis. This condition is commonly misdiagnosed because it is not considered as a possibility.

Malaria in Splenectomized Patients

Although it is generally believed that malaria may be associated with particularly severe infections in persons who have had a splenectomy, no clear evidence was found in a review[108] of this important question. Until this question is resolved, it is wise to advise visitors to the tropics who have had their spleens removed and splenectomized patients who live in regions where malaria is endemic to be particularly careful about continuing to maintain malaria prophylaxis.

Hyperreactive Malarial Splenomegaly Syndrome

Although splenomegaly is a feature of many tropical disorders, increasing evidence (particularly from work in East and West Africa and Papua New Guinea) indicates that a specific entity, formerly known as tropical splenomegaly syndrome, occurs widely throughout Africa, India, and Southeast Asia.[1,109,110] This condition is characterized by gross splenomegaly, high malarial antibody titer, and serum IgM levels at least two standard deviations above the local mean. The classic syndrome regresses after prolonged antimalarial prophylaxis with proguanil, a dihydrofolate reductase inhibitor marketed outside the United States as Paludrine.

Etiology and Pathophysiology. Evidence that malaria plays an important role in hyperreactive malarial splenomegaly (HMS) syndrome is increasing. Epidemiologic studies indicate that its prevalence is related to patterns of malarial transmission and that affected persons have a higher malarial antibody titer than do those who live in the same environment and are unaffected; this process seems to involve IgM rather than IgG. These observations, together with the partial clinical response to treatment with antimalarial drugs and the fact that persons with sickle cell trait seem to be partially protected, suggest that the condition probably results from an unusual form of immune response to chronic malarial infection. For this reason it is now commonly referred to as HMS.

With progressive splenomegaly, pooling of the formed elements of blood occurs, and in patients with particularly large spleens, a third to half of the total circulating red blood cell mass may be sequestered. Such sequestration produces a dilutional anemia that is made worse by an absolute increase in plasma volume. Pooling of neutrophils and platelets also occurs, and thus the hematologic picture is characterized by pancytopenia. No characteristic changes in bone marrow are seen.

Some evidence of a genetic predisposition to HMS exists.[111] A recent study in Ghana found that splenomegaly, high IgM levels, and anemia were more common in relatives of patients with HMS than in the general population, but no clear pattern of mendelian segregation was observed, thus suggesting that the cause in this population is likely to be complex and involve multiple genetic and environmental factors.[112] For some years researchers have debated about whether HMS is premalignant because it sometimes becomes refractory to antimalarial treatment, and it can also be associated with a lymphocytosis resembling chronic lymphocytic leukemia. Clonal rearrangements of the J_H region of the immunoglobulin gene have been noted in some patients whose clinical syndrome appears to be intermediate between HMS and chronic lymphocytic leukemia, thus suggesting that HMS has premalignant potential.[113]

Clinical Features. The clinical picture of HMS is typical and consists of massive splenomegaly, weight loss, and a variable degree of anemia.[109,110] Serum IgM levels are high, and a relative increase in T lymphocytes in peripheral blood may be seen. Serum may also show increased cold agglutinin titers and an increase in rheumatoid factor, antibodies to thyroglobulin and antinuclear factor, and circulating immune complexes.

The prognosis for patients with this condition is remarkably poor in parts of Africa, with up to 50% mortality in some populations. It is managed by long-term antimalarial prophylaxis, most commonly with proguanil.

Visceral Leishmaniasis (Kala-azar)

Leishmaniasis is an infection caused by intracellular protozoan parasites transmitted by various species of sandflies.[114,115] Human infections can result in three main forms of disease: cutaneous, mucocutaneous, and visceral (kala-azar). The important hematologic manifestations of leishmanial infection are found in the visceral forms.

The generalized form of leishmanial disease involves the liver, spleen, bone marrow, and lymph nodes and is caused by organisms belonging to the *Leishmania donovani* complex. The parent species, *L. donovani*, is found throughout Asia and Africa and can affect persons of all ages. However, the parasite that causes kala-azar in countries bordering the Mediterranean, in southern Europe, and in North Africa affects primarily young children and infants. It differs from *L. donovani* to such an extent that it warrants the designation of a special species and is called *Leishmania infantum*. Similarly, in the Western hemisphere, kala-azar is also a disease of very young children; the causative organism is *Leishmania chagasi*.

Although visceral leishmaniasis is primarily a disease of indigenous populations, it may be contracted on short-term visits. For example, in the United Kingdom it is being recognized increasingly after a return from Mediterranean holidays, and particularly in young children, it can cause considerable diagnostic difficulty; occurrences have been mislabeled as leukemia when the diagnosis of leishmaniasis was not considered. The risk for leishmaniasis is greatly increased in persons infected with HIV.[116]

Although the incubation period is usually 1 to 3 months, it can be as short as a few weeks. The onset is usually insidious and consists of fever, sweating, malaise, and anorexia, although a much more acute onset may be seen. As the disease progresses, the acute symptoms abate, but gradual enlargement of the spleen and liver ensues for several months. By this time the patient may have marked splenomegaly, cachexia, and anorexia. Generalized lymphadenopathy is also present.

Hematologic findings in later stages of the illness include anemia, neutropenia, and thrombocytopenia, which are manifestations characteristic of hypersplenism. The bone marrow is hyperplastic with dyserythropoietic changes, and the diagnosis can usually be made by finding Leishman-Donovan bodies—that is, macrophages containing intracellular organisms with characteristic staining properties (Fig. 38-8). The diagnosis can also be made by splenic or lymph node puncture.

Red blood cell survival studies and ferrokinetic analyses have suggested that hemolysis is the major cause of anemia in persons with leishmaniasis[117,118,119] but that plasma volume expansion also may be associated with the massively enlarged spleen.[119] Surprisingly, ferrokinetic

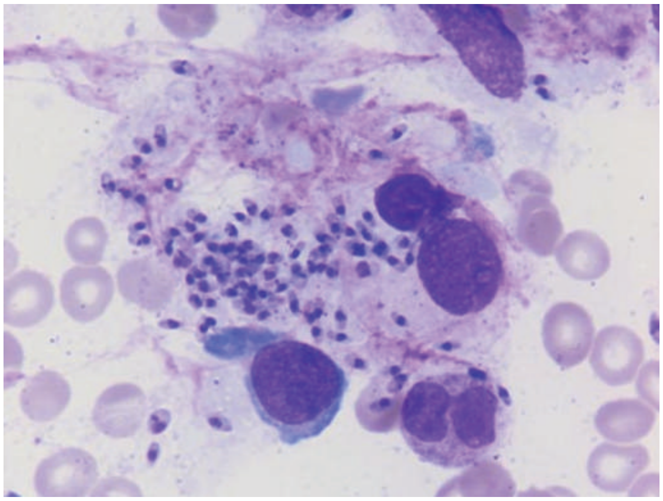

Figure 38-8 Leishman-Donovan bodies in the bone marrow of a 2-year-old child.

studies have shown very little evidence of ineffective erythropoiesis, but a reduced plasma iron level in the presence of greatly increased iron stores suggests that the reticuloendothelial hyperplasia is accompanied by abnormal iron retention by macrophages, typical of the anemia of chronic disorders.[119] This condition may limit the marrow response to hemolysis.

In babies or young children with acute visceral leishmaniasis, the clinical and hematologic findings may differ from those described earlier. For example, in Mediterranean populations a very rapid onset of anemia with severe hemolysis is commonly observed.[120] Occasionally both IgG and complement components are found on the red blood cells, but this finding is not consistent, and its significance remains to be determined. In most instances no evidence of immune hemolysis is found, and it appears that nonsensitized red blood cells are destroyed by macrophages recruited to the spleen and liver as part of the inflammatory response to the parasite. Severe neutropenia may also occur in young children, and this condition, together with dyserythropoietic changes in the marrow, marked erythrophagocytosis, and bizarre mononuclear infiltrates, may cause confusion with leukemia.

Schistosomiasis

The schistosomes are a group of trematodes that cause major health problems in many parts of the developing world.[121] The major human parasites include *Schistosoma haematobium*, *Schistosoma mansoni*, and *Schistosoma japonicum*. Schistosomiasis affects mainly children and young adults. Two hundred million people worldwide are estimated to have schistosomiasis, with 80% of them in sub-Saharan Africa.[122]

The location of adult worms in the human host varies with the parasite species: *S. hematobium* in the veins of the bladder, *S. mansoni* in the superior mesenteric veins, and *S. japonicum* in the inferior mesenteric veins. Sexual maturity of female schistosomes depends on their interaction with living male worms. Egg deposition occurs in the small venules of the bladder or portal venous system. When freshly deposited, the ova are partially developed. Hatching of the eggs leads to the liberation of miracidia. Further development occurs when miracidia penetrate a snail intermediate host. After two generations, cercariae are released that are capable of penetrating intact skin and migrating through tissues to reach their final home.

S. haematobium infections occur in Africa and the Middle East, whereas *S. mansoni* is found in Africa, the Middle East, and parts of South America. *S. japonicum* occurs in Japan and the Philippines, and together with the related species *Schistosoma mekongi*, it occurs in mainland Indochina.

The most consistent hematologic changes are found in association with *S. mansoni* infection. The acute phase is characterized by fever, myalgia, and progressive hepatosplenomegaly. At this time the most common finding in peripheral blood is eosinophilia. As the disease progresses, the patient may have massive hepatosplenomegaly associated with anemia, neutropenia, and thrombocytopenia.[123] Few good descriptions of the appearance of bone marrow in this condition are available, and the limited data suggest that the anemia is predominantly due to hypersplenism and hemodilution from the massive splenomegaly.

S. haematobium infection leads to urinary tract symptoms—in particular, hematuria and dysuria. The hematuria may be gross and persistent and may lead to iron deficiency anemia. In addition, affected children have typical features of the anemia of chronic disorders.

A major advance in the control of schistosomiasis is the availability of a highly effective drug, praziquantel, which is safe in both children and pregnant women. The cost of control programs may be reduced by combination therapy for schistosomiasis, gastrointestinal helminths, and filariasis. Major efforts to provide mass drug administration in high-burden areas have been undertaken[122] and have led to reductions in the intensity and prevalence of infection, but questions remain about the best strategy for long-term control, particularly in view of concerns about possible emerging resistance.[124]

Trypanosomiasis

Trypanosomal infections are a major cause of ill health throughout the world. The disease syndromes produced by these infections vary widely, but in general, they are divided into the American and African forms.[125-127]

American Trypanosomiasis (Chagas Disease)

American trypanosomiasis is a zoonosis caused by *Trypanosoma cruzi*, which is transmitted to humans by blood-sucking insects. It was first described by Carlos Chagas in 1909.

In its invertebrate host, *T. cruzi* grows extracellularly. Epimastigotes divide in the insect gut and differentiate into metacyclic trypomastigotes, which are the infective form for mammalian hosts. They are released close to the site of a bite and enter the host via the skin or mucous membranes. After invasion they enter cells, where they replicate as rounded amastigote forms that differentiate into trypomastigotes, which are released into the circulation and tissues. A variety of organs are involved, but the most important pathophysiologic result is a chronic cardiomyopathy.

Characteristic clinical findings are noted at each of these different stages of infection. After penetration of the skin, a local cutaneous lesion called an inoculation chagoma develops and is accompanied by swelling of the local lymph glands. Occasionally the route of inoculation is through the eye, where the initial lesion is characterized by unilateral conjunctivitis with edema of the eyelids. Invasion may or may not be followed by an acute phase consisting of fever, generalized lymphadenopathy, hepatosplenomegaly, and acute myocarditis.

The chronic phase of Chagas disease takes several forms. If cardiac involvement is predominant, a slowly progressive cardiomyopathy with heart failure, arrhythmias, and embolic complications is seen. In other patients, gastrointestinal symptoms predominate as a result of denervation and destruction of the myenteric plexus, which may give rise to megaesophagus or megacolon.

A congenital form of Chagas disease may occur. The organism can traverse the placental villi and from there be released into the fetal circulation. The most common

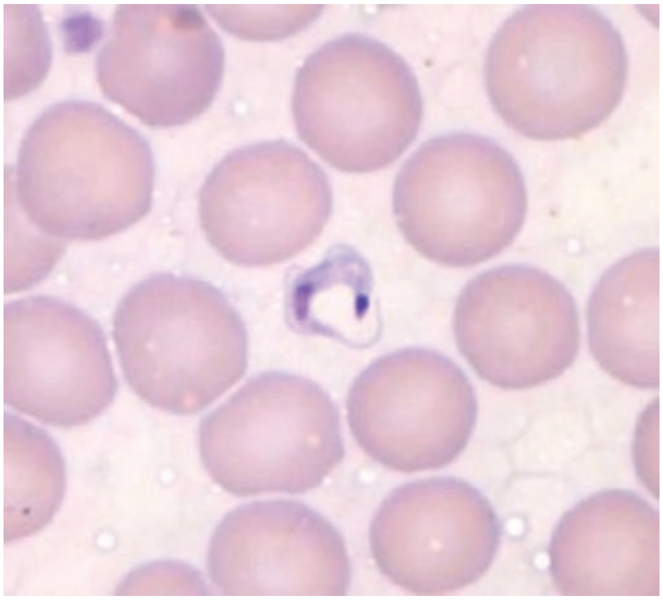

Figure 38-9 *Trypanosoma cruzi* parasite in the blood.

findings include growth retardation; hepatosplenomegaly; acute myocarditis; neurologic lesions, including a meningoencephalitic picture with tremors and convulsions; and, occasionally, a generalized hemorrhagic tendency with purpura or more widespread bleeding. The prognosis for patients with congenital Chagas disease is poor, and most infants die during the first week of life.

The hematologic changes in Chagas disease are nonspecific. In the acute phase, mild anemia and lymphocytosis may occur. At this stage the parasite can be found in the blood or in leukocyte concentrates (Fig. 38-9). Parasites may be concentrated by sedimentation of heparinized blood cells with the addition of phytohemagglutinin. Similarly, it is possible to find amastigote forms of *T. cruzi* in muscle or lymph node biopsy samples. The results of serologic tests for anti–*T. cruzi* IgM antibodies typically become positive about 20 to 40 days after the onset of symptoms.

African Trypanosomiasis

In Africa trypanosomiasis, conditions are caused by subspecies of the hemoflagellate *Trypanosoma brucei* known as *T. brucei gambiense*, which causes a chronic illness called sleeping sickness, and *T. brucei rhodesiense*, which is associated with a more acute illness. *T. brucei* is transmitted by the tsetse fly *Glossina*, in which it undergoes a variety of developmental changes.

A small nodule called a trypanosomal chancre forms at the site of the tsetse bite. Organisms may be isolated from this nodule. After this self-limited lesion subsides, the parasite invades and multiplies extracellularly in the blood, which leads to the systemic phase of the illness characterized by fever, lymphadenopathy, and splenomegaly. In the later phase of African trypanosomiasis, the central nervous system is invaded, which results in meningoencephalitis.

During the acute phase, normochromic normocytic anemia associated with hypoalbuminemia may be present. Occasionally patients have hemorrhagic manifestations and evidence of disseminated intravascular coagulation. The total white blood cell count is either normal or elevated with relative lymphocytosis. The sedimentation rate is markedly elevated, and circulating immune complexes may be present together with rheumatoid factor.

The parasite can often be demonstrated in thin or thick blood films stained with Giemsa or Field stain. Several concentration techniques have been developed to increase the likelihood of finding the parasite. A variety of immunodiagnostic tests are available, notably indirect immunofluorescence and enzyme-linked immunosorbent assay, but visualization of the parasite is necessary for a confident diagnosis. In the more chronic stage, it is important to examine cerebrospinal fluid, which often shows lymphocytosis, an elevated protein level, and the presence of morular cells of Mott or motile trypanosomes. High levels of IgM in cerebrospinal fluid may suggest the diagnosis in advanced disease if trypanosomes have not been found.

A novel test for African trypanosomiasis involves analysis of serum samples by mass spectrometry to detect distinct proteomic signatures; this test appears to provide more sensitive and specific detection than other diagnostic tests.[128]

Hookworm

It has been estimated that more than 900 million people are infected with hookworms.[129] The two main species that infect humans are *Ancylostoma duodenale* and *Necator americanus*, which are sometimes called the Old World and the New World hookworms, respectively. Both species are widely distributed in tropical and subtropical Asia and Africa. The prevalence of infection ranges from 80% to 90% in rural areas in the moist parts of the tropics, such as west Bengal, to 10% to 20% in relatively dry countries, such as those of the Middle East and Pakistan.

Both species of hookworm produce enormous numbers of eggs—approximately 20,000 per day per female. The eggs are discharged into the intestinal lumen, where they undergo a number of cell divisions before being passed in stool. Given appropriate conditions, the eggs develop further and hatch, with liberation of larvae. These free-living stages go through a series of developments designated L1 to L3, after which they penetrate the skin and the infective filarial larval forms migrate to the intestinal tract via the circulation, lungs, and respiratory tract. The final larval stage, L4, and the adult worms are found in the small intestine.

Hookworms attach to the mucosa of the upper intestine by their buccal capsules. Although they are found mainly in the jejunum, in persons with very heavy infections they may be distributed as low as the ileum. Attachment of the worm results in bleeding into the gastrointestinal tract.

The worms change their attachment site every few hours. Continuous or intermittent suction causes tissue and blood to be drawn into the worm's intestinal tract.[130] Only about 50% of the iron lost as hemoglobin into the gut may be reabsorbed, resulting in a marked increase in fecal iron concentration that is related directly to the worm load, which can be assessed by the fecal egg count. Direct recordings of blood loss have indicated values on the order of 0.03 mL/day per worm for *N. americanus* and up to 0.26 mL/day per worm for *A. duodenale*,[130] with the latter species tending to cause more profound levels of iron deficiency in the community.[131]

The hematologic findings in children or adults with heavy hookworm infections are characteristic. Because the condition is usually chronic, anemia is the major clinical feature. In severe cases, hemoglobin values of 2 to 5 g/dL are common.[132] The blood film shows the typical changes of iron deficiency anemia, such as microcytosis, hypochromia, and a normal reticulocyte count. The serum iron level is low, and iron is absent from bone marrow stores. Because of associated protein loss, affected children often have hypoalbuminemia.[132-135] Mild eosinophilia may be present[132] in patients with established illness, although very high eosinophil counts may occur during the phase of the illness in which the worms are migrating from the skin to the gastrointestinal tract (discussed later).

The diagnosis is made by analysis of stool for eggs. In persons with heavy infections, a fecal film can be examined directly after the sample is mounted in saline or iodine solution. In persons with lighter infections, concentration by zinc sulfate flotation is required.

Affected children require oral iron treatment to restore the iron stores, as well as treatment with anthelmintic drugs. Although many of these children are severely anemic, they usually have had chronic anemia for many years, and rapid restoration of the hemoglobin level is generally not required. However, in profoundly anemic children with high-output failure and associated hypoalbuminemia, it may be necessary to administer red blood cells slowly, together with appropriate diuretics. These children may have greatly increased blood volume, and it is easy to precipitate circulatory overload and cardiac failure. For patients with severe heart failure, an exchange transfusion consisting of removal of blood from one arm while infusing red blood cells into the other arm may be helpful. Whatever method is chosen, monitoring of the patient's central venous pressure is essential.

In recent years a growing number of tropical countries have made concerted efforts to reduce the effects of hookworm infection through use of anthelmintic strategies in the community. For example, mass administration of mebendazole to 30,000 school children in Zanzibar was estimated to prevent 1260 cases of moderate to severe anemia and 276 cases of severe anemia in 1 year, although it appeared that at least two doses per year would be necessary to maintain this level of protection, thus raising the issue of long-term sustainability.[136]

Bartonellosis

Bartonellosis (also known as Carrión disease and Oroya fever) is an infectious disease that is endemic in the western Andes of Peru and is seen occasionally in Colombia and Ecuador.[137] It results from infection by an aerobic, gram-negative bacillus, *Bartonella bacilliformis*. It is usually transmitted through a sandfly bite. After inoculation, the organism multiplies in endothelial and red blood cells. In severe cases of the disease, almost 100% of red blood cells are infected with numerous bacteria (Fig. 38-10). Hence the major feature of the disease is profound anemia resulting from the infection and subsequent phagocytosis of red blood cells. Although the precise mechanisms of the anemia are not fully understood, it seems to have many of the features of anemia of acute malarial infection. Survival of infected and noninfected red blood cells is shortened, and a limited response to the hemolysis associated with dyserythropoietic changes in the bone marrow is seen.

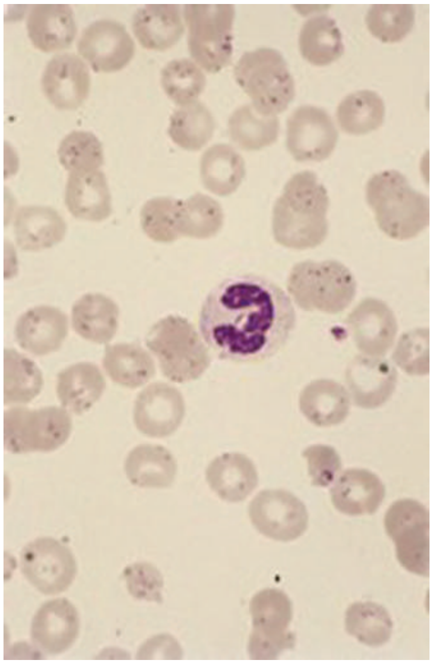

Figure 38-10 Bartonellosis in the peripheral blood.

The disease has two stages, anemic and eruptive, with an asymptomatic period between the stages. After an incubation period of approximately 60 days, the onset of the condition is acute and consists of malaise, chills, fever, and headache. The clinical picture is then dominated by severe hemolytic anemia associated with hepatosplenomegaly, lymphadenopathy, and, occasionally, a fine petechial rash. In the later eruptive stage, nodule lesions of varying size appear on the face, trunk, and limbs. Arthralgia and fever may also be present. The lesions, which are widespread on the arms and legs, may be confused with leprosy, yaws, or even Kaposi sarcoma. Although the infection is often present for a prolonged period, the eruptive phase tends to regress spontaneously.

During the anemic stage, moderate to severe hemolytic anemia is seen with reticulocyte counts in the 5% to 10% range. The organisms can be seen on thick and thin blood films stained with Giemsa, Wright, or related stains. The bone marrow is hyperactive with dyserythropoietic changes. The white blood cell count is not usually elevated, but thrombocytopenia is common.

The principal complication of this disease, apart from profound anemia, is superinfection with other organisms, particularly *Salmonella typhi* and *Mycobacterium tuberculosis*. Fortunately, *B. bacilliformis* is extremely sensitive to chloramphenicol, penicillin, and tetracyclines. Supportive treatment includes regular transfusion through the anemic phase of the illness.

Complex Hematology of Childhood HIV Infection in Developing Countries

The devastating impact of perinatally acquired HIV infection in an increasing number of developing countries is mirrored by the complexity of the hematologic complications of this disease in these populations. In some central African countries, seroprevalence rates in pregnant mothers in 1990 ranged from 20% to 30%, and in several other countries they exceeded 10%.[138] In India and Southeast Asia, the figures are presently much lower than this but are rapidly rising. Perinatal transmission rates have been difficult to establish with certainty but seem to be considerably higher than in the West. In 1989, an estimated figure in Zaire was 39%.[139] Although some children are infected through breastfeeding, the current consensus is that the benefits of breastfeeding probably outweigh the risk in countries where infectious diseases are the major cause of infant mortality.

The clinical picture of childhood HIV infection in the tropics does not differ greatly from that seen elsewhere, except that protein-energy malnutrition occurs much earlier. Tuberculosis and measles, both major causes of mortality by themselves, are more severe in HIV-infected children, but surprisingly, the severity of malaria does not seem to be affected. In Malawi, it is estimated that approximately half of perinatally infected infants die in the first year of life,[140] a considerably earlier mortality than that seen in the West.[141]

HIV infection provides yet another example of the complex pathogenesis of hematologic problems in the tropics. The virus can infect hematopoietic precursors,[142,143] as well as bone marrow macrophages and stromal fibroblasts, which may explain the marked dyserythropoiesis that is commonly observed in the bone marrow of affected children; however, these changes may also be complicated by opportunistic infection, malnutrition, and drug toxicity. Anemia with a low reticulocyte count and a microcytic hypochromic blood picture is common and may reflect both coexistent iron deficiency and the anemia of chronic disorders.[141,144,145] Although HIV may cause immune thrombocytopenia early in the course of the disease, it is not regarded as an adverse prognostic feature. Thrombocytopenia may also be accompanied by microangiopathic hemolytic anemia as part of thrombotic thrombocytopenic purpura, which, in the context of HIV infection, responds well to plasma infusion. Later, in addition to the progressive lymphopenia that characterizes acquired immunodeficiency syndrome, both reduced production and increased cellular clearance may contribute to neutropenia and thrombocytopenia.[145,146] Finally, advancing immunodeficiency contributes to a greatly increased risk for lymphoid neoplasms, particularly lymphoma.

The wide spectrum of hematologic complications associated with HIV and the high prevalence of infection make HIV testing an essential part of the investigation of cytopenia in most tropical areas. One of the most difficult dilemmas that HIV infection poses for pediatricians in the tropics is management of a child with life-threatening anemia. The conventional approach would be blood transfusion, but in many regions blood transfusion is now a major risk factor for HIV infection that is not adequately prevented by the available screening programs.[147,148] This problem is discussed further in a later section of this chapter.

TROPICAL EOSINOPHILIA

The structure and function of eosinophils are described in Chapter 21. Here the importance of eosinophilia in the tropics is discussed.

After anemia, eosinophilia is probably the next most common hematologic abnormality in children in the tropics.[149] An increase in eosinophils in bone marrow and peripheral blood, as well as in tissues, is a major feature of infections caused by worms that migrate through extraintestinal organs. A strong association exists between eosinophilia and infection with tissue nematodes, trematodes, or cestodes. In contrast, however, there is no well-documented evidence that worms that do not invade tissues or protozoal infections are associated with elevated eosinophil counts.

Some common causes of eosinophilia in the tropics are summarized in Box 38-1. A functional role for eosinophils in host protection against some invasive helminths has been demonstrated. For example, incubation of human eosinophils with the larval forms of *S. mansoni* or *Trichinella spiralis*, together with specific antibodies or complement, causes the destruction of these organisms. These in vitro studies have been confirmed by in vivo experiments in mice depleted of eosinophils; animals treated in this manner lose resistance to these helminths. It appears that killing of these organisms is initiated by attachment of eosinophils to the parasite surface, followed by extracellular degranulation and deposition of electron-dense material.

Box 38-1 **Causes of Eosinophilia in Tropical Populations**

TISSUE NEMATODES

- *Wuchereria bancrofti*
- *Loa loa*
- *Onchocerca volvulus*
- *Ankylostoma braziliense*

- *Trichinella spiralis*

TISSUE TREMATODES

- *Schistosoma*
- *Fasciola hepaticum*

TISSUE CESTODES

- *Echinococcus granulosus*

An absolute elevation in the peripheral blood reticulocyte count may occur in any of the conditions listed in Box 38-1. However, the term *tropical eosinophilic syndrome* was first used in the 1940s to describe patients with a paroxysmal cough and wheezing, particularly at night, scanty sputum production, weight loss, low-grade fever, lymphadenopathy, and extreme blood eosinophilia (>3000/μL). Later this syndrome was discovered to be due to filarial infection.

Hypereosinophilic syndrome is seen in children or young adults and is found most commonly in India, Indonesia, Sri Lanka, Pakistan, and Southeast Asia, although it may occur in any area where human filariasis is common.[150-153] In addition to typical clinical and hematologic findings, these patients have very high levels of serum IgE together with increased levels of specific antifilarial antibodies. Although it is usually easy to make this diagnosis in a tropical setting, if patients with these symptoms return to nontropical countries, other conditions that cause eosinophilia must be considered, including chronic eosinophilic pneumonia, allergic aspergillosis, vasculitic syndromes, and idiopathic hypereosinophilic syndrome. The major distinguishing features of tropical hypereosinophilic syndrome are a marked elevation in antifilarial antibody and very high IgE levels. It may be possible to identify filaria on blood films. Traditionally, better results have been obtained with films prepared from blood samples taken at night, although some studies suggest that this step may not be necessary.[153]

What is the best approach to determine a diagnosis in a child who has spent time in the tropics and who has persistent eosinophilia? It is important to determine which parts of the tropics have been visited. A careful respiratory history should be obtained. Detailed studies of stool for cysts and ova should be performed several times by an experienced observer. Serologic studies for *Filaria*, *Toxocara*, and *Trichinella* infection should be carried out, and immunoglobulin levels should be determined. If a diagnosis has not been determined after these investigations, it is important to exclude nontropical causes of eosinophilia, including collagen vascular disease, allergy, drug reactions, lymphoma, and leukemia associated with an eosinophil response. It may be necessary to initiate a trial of the antifilarial drug diethylcarbamazine under careful medical supervision as part of the diagnostic workup.

HEMATOLOGIC ASPECTS OF MALABSORPTION IN THE TROPICS

One of the major difficulties in discussing the problem of malabsorption in the tropics is definition.[154] A large proportion of people in tropical climates, both indigenous populations and expatriates who have lived and worked in rural areas, have mild abnormalities of the intestinal mucosa that are often associated with impairment of absorption. These structural and functional alterations of the gut have been called *tropical enteropathy*.[155-157] It is likely that they reflect an adaptation to life in the contaminated environment of the tropics with its recurrent enteric infections and peculiarities of diet. Interestingly, similar morphologic lesions have been demonstrated in the colon of otherwise healthy residents of southern India. After expatriates return to temperate climates, these changes in the gut revert to normal.[158]

The more severe malabsorption syndromes, sprue and postinfective malabsorption, are associated with chronic diarrhea, wasting, and a variety of hematologic changes.

The term *sprue* was first coined by the English physician Manson while working in China; it is an Anglicization of the Dutch term *indische sprouw*. During the nineteenth and twentieth centuries, tropical sprue was thought to be a disease of expatriates, but during World War II it became apparent that similar syndromes commonly occur in indigenous populations. The occurrence of severe malabsorption syndromes is not distributed evenly in the tropical world.[158-160] They are particularly common in the Indian subcontinent, Burma, Malaysia, Vietnam, Borneo, Indonesia, and the Philippines. They are also seen in the West Indies, in parts of Central America (particularly Puerto Rico, Cuba, and the Dominican Republic), and in northern parts of South America. A few reports have come from the Middle East and temperate areas. Tropical Africa seems to be spared.

These syndromes are believed to originate from an infection.[161,162] They usually start as an acute attack of diarrhea, which then becomes chronic. Many well-documented epidemics of sprue have been reported both in southern India and in the Philippines among American military personnel. However, despite a vast amount of work and the establishment of units specifically assigned to study the problem, no organism has been isolated that could even approach meeting Koch's postulates. It may be that these disorders can follow infection with a variety of agents, but the reason for the peculiar geographic distribution remains unexplained. Remarkably, genetic factors have been almost totally ignored in the investigation of this disease.

Tropical malabsorption syndromes can occur in persons of any age. They are characterized by intermittent diarrhea, weight loss, and anemia. Varying degrees of mucosal damage are found upon biopsy of the small intestine, although an absolutely flat mucosa, as seen in gluten-induced enteropathy, is rare. Hematologic findings in patients with tropical malabsorption syndromes vary considerably. In persons with more advanced disease, megaloblastic anemia is common; it is usually caused by folate deficiency but may also be complicated by vitamin B_{12} deficiency. Frequently, bizarre mixed pictures of iron and folic acid deficiency are found.

Interestingly, although much of the data have been derived from uncontrolled studies, many of the symptoms and hematologic changes associated with these syndromes can be reversed by a course of oral tetracycline. However, recovery is much more rapid if folate or vitamin B_{12} treatment is provided as well.

In a tropical setting, malabsorption can also result from colonization of the small bowel by specific parasites, including *Giardia lamblia*, *Strongyloides stercoralis*, *Cryptosporidium*, and others. Furthermore, abdominal tuberculosis with malabsorption is particularly common, and in Africa, HIV infection may be an important cause of malabsorption.[163,164] The local name "slim disease" acknowledges the severe wasting that can occur with HIV infection.[163]

Hematologists without experience in the tropics should be aware that the clinical and hematologic findings of tropical malabsorption syndromes can be extreme. In young children in particular a good history of diarrheal illness may not always be available, and in many tropical populations, recurrent diarrheal illness is the norm anyway. In addition to producing anemia, folate deficiency may give rise to severe neutropenia and thrombocytopenia with associated infection or bleeding. If intercurrent infection is present, as is often seen in severely affected children, the bone marrow appearance may be deceiving, although some megaloblastic change nearly always occurs even if overall the bone marrow is much less hyperplastic than is usually observed with folate or B_{12} deficiency in Western settings.

A major diagnostic problem that is often encountered in children who return from the tropics with persistent diarrhea and malabsorption is determining whether they have postinfective malabsorption or celiac disease. If the symptoms do not resolve, it may be necessary to initiate a trial of a gluten-free diet and then reintroduce gluten at a later date while monitoring progress with repeated small bowel biopsies.

HEMOSTATIC FAILURE AS A MANIFESTATION OF SYSTEMIC DISEASE IN THE TROPICS

Many tropical infections or other hazards produce serious bleeding disorders. Malaria was considered in an earlier section. A few other causes of bleeding disorders that are seen in the tropics are discussed in this section.

Dengue

The dengue viruses are four antigenically related but distinct organisms that are transmitted to humans by mosquitos of the species *Aedes aegypti*.[165] The clinical manifestations of this very common infection vary in different parts of the world. In American, African, and Indian populations the disease is characterized by classic dengue fever, but in Southeast Asia a much more serious condition, dengue hemorrhagic fever (DHF)/dengue shock syndrome (DSS), develops in many children. The latter condition develops in infants born to dengue-immune mothers during initial infections or in children older than 1 year during secondary infections. It appears that this curious paradox reflects enhancement of dengue viral infection in mononuclear phagocytes mediated by subneutralizing concentrations of dengue antibody.

The pathophysiologic course of DHF/DSS is quite remarkable.[165,166] Dengue viruses appear to be parasites of mononuclear phagocytes. Furthermore, they use antibody as a specific receptor for gaining entry to these cells. Such antibodies are known as infection-enhancing antibodies. Epidemiologic studies have shown that children 1 year or older always have detectable dengue antibody before acquiring a subsequent infection that results in DHF/DSS. Infants who acquire dengue antibody passively from their mothers are also at risk for development of the syndrome. DHF/DSS is characterized by simultaneous activation of the complement and hemostatic systems, together with a marked increase in vascular permeability.[166-168] It appears that complement activation follows both the classical and alternative pathways. The hemostatic abnormalities include gross thrombocytopenia, prolonged bleeding time, elevated prothrombin time, and a reduction in the levels of factors II, V, VII, and IX, together with marked hypofibrinogenemia and an increase in fibrin degradation products. The abnormalities in vascular permeability are characterized by an elevated hematocrit, normal or low serum protein levels because of selective loss of albumin, and variable serous effusions.

Precisely what triggers these remarkable events is not clear. However, it seems likely that the mediators are the product of dengue virus–infected mononuclear phagocytes. Studies in Thailand have suggested that low levels of heterotypic neutralizing antibody from a single previous infection prevent the illness in persons who acquire dengue grade II infections.[165,168] On the other hand, children who have circulating dengue-enhancing antibodies but no neutralizing antibodies are at high risk.

Once DHF has been triggered, the immune disturbance is not confined to antibodies. Both the $CD4^+$ and $CD8^+$ subpopulations of T lymphocytes are more intensively activated in persons with DHF than in persons with uncomplicated dengue fever.[169] High levels of TNF and other procoagulant cytokines may also contribute to the pathologic changes.[170] A further factor might be antibodies to plasminogen, which are found in a significant proportion of dengue infections, particularly if hemorrhage is present.[171] These antibodies are thought to arise because of structural homology between plasminogen and the dengue envelope glycoprotein.[172] Findings in Vietnamese children with DSS suggest that rather than causing true disseminated intravascular coagulation, the virus may act to directly degrade fibrinogen and thereby result in secondary activation of procoagulant homeostatic mechanisms.[173]

The clinical findings of DHF/DSS consist of fever, malaise, and anorexia, and about 2 to 5 days later a second phase occurs in which widespread hemorrhagic phenomena are observed, including purpura, large spontaneous ecchymoses, and bleeding from previous venipuncture sites. These children then enter a phase of profound shock. The hematologic findings are characterized by a normal or even high hematocrit associated with gross thrombocytopenia and evidence of disseminated intravascular coagulation.

The fact that the most serious pathophysiologic mechanism in this disease is fluid loss rather than hemorrhage has focused attention on the development of treatment regimens similar to those used for the management of severe diarrheal illnesses in children in the tropics. A study in Vietnamese children concluded that initial resuscitation with lactated Ringer solution was appropriate for children with moderately severe DSS, whereas hydroxyethyl starch resulted in fewer adverse reactions than did dextran for colloid treatment of severe DSS.[174] Clinical trials of heparin treatment to counteract disseminated intravascular coagulation have not produced impressive results.

Other Viral Hemorrhagic Fevers

Severe hemorrhagic fevers caused by viruses occur throughout the tropical world and are encountered on every continent except Australia and North America.[175] These fevers are the result of ribonucleic acid viruses of four distinct families, each of which is a zoonosis with typical epidemiologic features. These viruses are transmitted by a variety of agents, including tics and mosquitos. In many instances the reservoirs and vectors are unknown. These diseases are associated with specific clinical entities in different parts of the world, such as Rift Valley fever, Lassa fever, Argentine hemorrhagic fever, Bolivian hemorrhagic fever, and others.

Many of these conditions are accompanied by hemorrhagic diatheses of varying severity ranging from mild purpura to severe hemostatic failure.[176] As with dengue, shock is a major feature and is often associated with an elevated hematocrit. The bleeding manifestations reflect both increased vascular permeability and consumptive coagulopathy. Few extensive coagulation studies have been performed in patients with these disorders, although disseminated intravascular coagulation has been implicated as the basis for the hemostatic failure.

Snake Bite

Snake bite is an important and neglected problem in the rural tropics; its incidence is underestimated because of the lack of reliable epidemiologic data.[177] In northern Ghana, the carpet viper (*Echis* complex of species) is responsible for some 86 bites per 100,000 population per year, with 28% mortality. This particular snake, whose geographic range extends throughout the northern half of Africa and the Middle East to India, probably bites and kills more people than any other species. In the Indian subcontinent, the most important species are the cobra (*Naja naja*), the common krait (*Bungarus caeruleus*), Russell's viper (*Vipera russelli*), and *Echis* species. In Sri Lanka about 60,000 bites and 900 deaths (6 per 10,000 population) occur each year. In Southeast Asia, the Malayan pit viper (*Calloselasma rhodostoma*), *Daboia russelli*, and green pit vipers cause most bites and deaths. In Burma, Russell's viper bite has been the fifth major cause of death, with an annual mortality of about 15 per 100,000 population. Snake bite is also a common public health problem in Central and South America.

The hematologic complications of snake bite are a reflection of the complex chemistry of venoms.[178-180] Although much work remains to be done, at least some components of snake venom have been well defined. Venom may contain 20 or more different components. More than 90% of the dry weight of venom is protein in the form of enzymes, nonenzymatic polypeptide toxins, and nontoxic proteins. The mechanisms of envenomation have been most clearly defined for some of the venom procoagulants. For example, *V. russelli* venom contains a glycoprotein that activates factor X and an arginine ester hydrolase that activates factor V. *Echis* venom contains a zinc metalloprotein called ecarin that activates prothrombin. Many crotaline venoms contain proteases that cleave fibrinogen (e.g., arvin and reptilase). Some venoms contain phospholipase A_2 (lecithinase), which probably contributes to their neurotoxicity, cardiotoxicity, and hemolysis and is also responsible for increasing vascular permeability.

After a snake bite, swelling and bruising of the limb result from increased permeability induced by proteases, phospholipase, polypeptide toxins, and hyaluronidase, as well as by endogenous activators released by the venom such as histamine, 5-hydroxytryptamine, and kinins. The acute hemostatic failure that may follow envenomation is mediated in several ways.[181,182] Bites from snakes that produce procoagulants that activate factors V or X or prothrombin are associated with a rapid consumptive coagulopathy. In other instances rapid defibrinogenation may occur that is due to either direct attack on fibrinogen or activation of the endogenous fibrinolytic system. Thrombocytopenia results from either aggregation or consumption. The bleeding is potentiated by damage to vascular endothelium. The combination of defibrination, thrombocytopenia, and increased vessel wall permeability leads to massive bleeding, which is a common cause of death.

Although, as mentioned earlier, many venoms are hemolytic in vitro, massive intravascular hemolysis is seen rarely and usually in association with bites by *V. russelli*.

Management of snake bite includes supportive treatment, careful correction of the coagulation abnormalities, appropriate respiratory support if the venom is associated with neurotoxins, and judicious use of appropriate antivenin. Hemostatic disturbances usually respond well to antivenin treatment, and replacement therapy with fresh whole blood, fresh frozen plasma, specific factors, or platelet concentrates is not generally required. Even though a theoretical case can be made for the use of heparin in patients bitten by Russell's viper, particularly if there is definite evidence of disseminated intravascular coagulation, thus far clinical trials have not shown any benefit.

Although the long-term prognosis for persons who recover from a snake bite is good, work in Burma has shown that chronic pituitary failure and renal failure may develop later. These conditions are believed to be caused by infarction of the pituitary gland during the phase of intravascular coagulation, which is similar in pathophysiology to that observed after childbirth and in this setting is called Sheehan syndrome.[183] It may be accompanied by a mild normochromic anemia.

GEOGRAPHIC VARIABILITY IN THE DISTRIBUTION AND EXPRESSION OF HEMATOLOGIC DISEASE

In addition to the unique hematologic problems caused by disorders that are specific to the tropics or other parts of the developing world, the pattern of distribution of primary disorders of the blood varies considerably among different populations. Furthermore, some hematologic syndromes, as yet ill defined, are unique to certain parts of the developing world.

Lymphoma and Leukemia

The pathophysiologic and clinical features of the lymphomas and childhood leukemias[184,185] are described elsewhere in this book. Burkitt lymphoma is endemic throughout large regions of sub-Saharan Africa and in Papua New Guinea. In Burkitt's classic descriptions of the tumor, he pointed out that its occurrence is related closely to altitude, temperature, and rainfall, features that are similar in sub-Saharan Africa and Papua New Guinea. Although this distribution—together with work relating this B-cell tumor to infection with Epstein-Barr virus and evidence for loss of immunologic control of Epstein-Barr virus during acute attacks of malaria[176,186]—relates the prevalence of the tumor to malaria, this is certainly not the whole story. For example, Burkitt lymphoma is not found in Zanzibar, although it is very common in the coastal regions of neighboring Tanzania.

The T-cell leukemia/lymphoma syndrome, first recognized in southern Japan and now known to be due to infection with human T-cell leukemia/lymphoma virus type 1 (HTLV-1), has a very restricted distribution in southern Japan and the Caribbean.[185] It is not yet clear which particular lymphocyte populations are involved in the very common histiocytic lymphomas that occur throughout the Middle East and across parts of Central and South America.

The curious syndrome of primary upper intestinal lymphoma (Mediterranean lymphoma) and immunoproliferative disease of the small intestine must be distinguished from the rare primary intestinal lymphomas that occur sporadically throughout the world, usually in elderly patients.[187,188] In endemic regions, primary upper intestinal lymphoma and immunoproliferative disease of the small intestine occur in much younger age groups, usually of poor socioeconomic background. The pathologic lesions are found predominantly in the upper part of the small intestine and are associated with a clinical picture characterized by malabsorption, which often precedes development of the tumor.

Although this condition is still known as Mediterranean lymphoma, it was first described in Peru. However, the largest epidemic area is the region of the Mediterranean and the Middle East, and many cases have now been reported from Israel, Lebanon, Iraq, Syria, and Iran, as well as Greece.

Studies of the population distribution of classic Hodgkin disease have also shown some discrepancies.[184,189] High rates are found in most affluent westernized countries, and lower rates are found in poorer countries and the tropics; this finding does not seem to be attributed entirely to ascertainment bias. Interestingly, particularly low rates are seen in Japan, as well as in China, India, and Malaysia. In addition, considerable variations in age distribution and histologic subtype exist in different parts of the world. In poorer or lesser developed countries, Hodgkin disease occurs at a younger age and is usually the histologic type with a poorer prognosis.

Some interesting differences in rate of occurrence and type of acute leukemia throughout the world are also seen.[184,190] In North America and Europe and in all other westernized populations, acute lymphoblastic leukemia (ALL) accounts for a high proportion of cases of acute leukemia in children between the ages of 2 and 5 years. In contrast, ALL is uncommon in the tropics, particularly in sub-Saharan Africa, where Burkitt lymphoma is the predominant childhood tumor. On the other hand, in older children the incidence of acute myeloid leukemia and various subtypes of ALL is similar to that in Western societies.

Hereditary Blood Disorders

The distribution of hemoglobin disorders in the world is described elsewhere in this book. The reasons for their remarkably high frequency include heterozygote protection against malaria, a high frequency of consanguinity in many of the high-frequency regions, and the epidemiologic transition toward a reduction in childhood mortality as a result of malnutrition and infection, allowing children with these conditions who previously would have died early in life to survive long enough to be evaluated for treatment.[191] A remarkable heterogeneity in the frequency of these disorders has recently been shown in many high-frequency populations, even within short geographical distances,[192] which may reflect variation in malaria transmission in these populations. It has also been found recently that strong epistatic interactions occur between protective polymorphisms to malaria. For example, whereas persons with the sickle cell trait or α thalassemia trait are protected against malaria, persons who inherit both traits lose this protection.[193] By modeling these interactions, it is becoming possible to provide further information about the mechanism for the heterogeneous distribution of these disorders.[194] For economic, environmental, and cultural reasons, the presentation, diagnosis, and management of these conditions raise problems in many developing countries that are completely different from the problems encountered in developed countries.[191]

Remarkable differences have been found between high-frequency regions with regard to other common hematologic disorders that have reached a high frequency as a result of malaria resistance. For example, although G6PD deficiency is always associated with drug-induced hemolysis and favism, it is also associated with a high frequency of neonatal jaundice in some, but not all, populations; the reason for this discrepancy is still unknown.[195] Another example is the extremely high frequency in Melanesia of ovalocytosis, a condition that is relatively rare in Western populations. This condition is asymptomatic in heterozygotes, although the absence of reported homozygotes suggests that it may have a much more severe phenotype. Evidence clearly shows that it has reached its high frequency in Melanesia by providing protection against malaria, particularly cerebral malaria.[196]

Aplastic Anemia

Although more data are needed for confirmation, evidence is growing that aplastic anemia, particularly in childhood, is much more common in parts of Southeast Asia and South America than in developed Western countries.[197] The ease of availability of potentially toxic agents such as chloramphenicol may be reflected by this finding but is probably not the whole story. The possibility exists that that aplastic anemia reflects the action of an unidentified infectious agent. This challenging question requires further detailed prospective studies because a full hematologic workup, including a bone marrow trephine biopsy, is rarely available in many parts of the world, even at tertiary referral hospitals.

Hematologic Disorders Unique to Certain Countries

A number of ill-defined hematologic disorders appear to be common to particular countries. For example, a well-recognized disorder called acquired prothrombin complex deficiency occurs in Thailand and is seen mainly in infants who have been breastfed.[198] Despite a great deal of investigation, the cause is not yet known, although it is suspected that mothers may have ingested substances antagonistic to prothrombin.

A very curious condition called "acquired platelet dysfunction with eosinophilia," which is also seen in Thailand,[199] is a pediatric disorder characterized by bleeding and ecchymoses. The disorder is associated with eosinophilia and abnormal platelet function test results. The cause is unknown, with current efforts focused on attempts to define a parasitic cause.

In India an increase in hemolytic disease of the newborn that appears to be due to fetomaternal ABO incompatibility has been noted.[200] Evidence is increasing that this condition may be related to the administration of tetanus toxoids to pregnant women to prevent the major problem of tetanus neonatorum in that population because a marked increase occurs in the maternal titer of anti-A/anti-B antibodies after injection of the tetanus toxoid.

ASPECTS OF CLINICAL MANAGEMENT

Treatment of Severe Anemia in the Tropics

The definition of severe anemia depends on the clinical context, and the normal level of hemoglobin in the community must be considered. In an African child with malaria, a hemoglobin level of approximately 5 g/dL is commonly used as the criterion for transfusion, although a transfusion would normally be given sooner if the parasitemia were extremely high. The fatality rate for severe malarial anemia varies widely between clinics, but a typical figure is approximately 7%.[201] Until recently, most tropical pediatricians have endeavored to improve survival by improving the availability of transfusions.

The situation has altered dramatically as a result of the significant risk of HIV infection that now accompanies blood transfusion in many tropical regions.[147,202] Apart from the logistic and financial difficulties of screening blood donations, these screening procedures are an unreliable means of preventing transfusion-associated HIV infection in the developing world[148] (discussed later). Other problems with blood transfusion also exist that tend to be ignored. Crossmatching can be erratic in a clinic with inadequate resources, and the infusion is often unsupervised. Occasionally the consciousness level of a child with malaria deteriorates dramatically after the transfusion. Such occurrences are rare, but there are theoretical reasons why transfusion might worsen sequestration, such as the blood group favoring the formation of erythrocyte rosettes.[203]

The need to define the clinical criteria that make transfusion absolutely essential is urgent. Decision trees have been devised,[204] but the underlying risk-benefit equation may vary from place to place, and a meta-analysis found no clear evidence of benefit for transfusion in anemic children whose conditions are clinically stable.[205] One issue that has become clear is the prognostic importance of respiratory distress. For example, in Kenyan children, malarial anemia rarely causes death unless respiratory distress is present,[206] and the only clear evidence that blood transfusion is beneficial is seen in the group of children who have both anemia and respiratory distress.[207]

Investigations into the clinical physiologic course of severe malarial anemia in African children have yielded important insight into the management of this condition. Lactic acidosis appears to be the main cause of the relationship between anemia and respiratory distress,[208] and a substantial oxygen debt is present.[209] Rapid transfusion may be lifesaving, not only because it increases hemoglobin but also because volume repletion reduces acidosis.[208] A carefully conducted study in Kenya showed no evidence that rapid transfusion was likely to cause fluid overload, although in different parts of the world, different pathophysiologic factors may be operative.[210] However, it is now clear that bolus fluid supplementation of severely ill children on admission may result in higher mortality (discussed later). Therefore ill children should be carefully assessed clinically and appropriate fluid or blood transfusion should be administered to correct hypovolemia or severe anemia.

With the steady increase in levels of resistance to antimalarial drugs worldwide, the incidence of severe childhood anemia in the tropics is expected to increase. As the criteria for transfusion become stricter, the need exists for more data on optimal hematinic therapy for children with malarial anemia. The practices of pediatricians vary, but many pediatricians prescribe both iron and folic acid in addition to antimalarial therapy. One concern has been that iron deficiency may help suppress parasite growth, and in some studies[211,212] (but not others[15]), iron repletion has been found to increase the risk for subsequent infection. Another concern has been that folic acid supplements might reduce the efficacy of the antifolate drugs that are increasingly being used to treat chloroquine-resistant malaria in the community.[213] These issues were addressed in a study of moderately anemic Gambian children with *P. falciparum* infection.[214] Supplementary iron therapy was found to result in a small but significant improvement in hemoglobin levels after 1 month and did not increase the risk for reinfection within this period. Folic acid supplements failed to improve hemoglobin levels and increased the risk for parasite recrudescence if sulfadoxine-pyrimethamine was used to treat the infection. However, it cannot be assumed that these findings would necessarily apply to regions with different rates of malarial transmission and different nutritional problems, and the need for locally based research into this type of problem cannot be overemphasized.

Problems with Blood-Borne Infection and Blood Transfusion

The risk of contracting an infection after blood transfusion is increasing and is becoming a major economic burden for developing countries. Whereas the most important infections are those resulting from blood-borne HIV and hepatitis B and C viruses, the incidence of other infections is increasing. As previously mentioned, although donor screening has had a major effect in reducing the occurrence of HIV infection in patients who are receiving regular blood transfusions, such as patients with thalassemia, even if blood is screened adequately, the risk for infection remains. Hepatitis C is becoming a major problem throughout the southern Mediterranean region, the Indian subcontinent, and Southeast Asia, whereas hepatitis B remains a problem in many of the poorer countries. With the reappearance of malaria as a major problem in parts of the Indian subcontinent and Southeast Asia, posttransfusion malarial infection is increasing. Indeed, in many clinics it is becoming standard practice to treat recipients of transfusions with antimalarial drugs prophylactically.

In addition to these common viral and parasitic infections, the risk of blood-borne disease caused by other bacteria and parasites must always be considered, particularly in places where these infectious diseases are endemic. For example, Chagas disease is often transmitted through blood transfusion, although remarkably, pretreatment of blood with gentian violet seems to result in a major reduction of this complication. In parts of South America, transfusion-borne infections with *Bartonella* may occur. Diseases associated with HTLV-1 and HTLV-2, notably tropical spastic paraparesis and adult T-cell leukemia, which seem to be restricted mainly to the Caribbean and certain Japanese populations, can also be transmitted by blood transfusion.

Clearly, screening programs must be tailored to the particular infections that are common in individual communities, and blood should be administered only when absolutely necessary in these populations.

Management of Imported Malaria

The most important part of the management of malaria is to be constantly aware of the possibility of the diagnosis.[215] Obtaining an accurate travel history is critical. Children who have flown from one nonmalarious region to another may have had a brief stopover during which they could have been infected. It is vital to obtain a detailed account of all countries visited and the use of malaria prophylaxis. Clinical symptoms are usually seen within a month of infection, but they can occasionally appear after several months if the infection has been partially suppressed by a prophylactic drug with a long half-life, such as mefloquine. In a child who has previously been infected with *P. vivax* or *P. malariae* and in whom parasites in the dormant stage in the liver have not been eradicated, symptoms may recur years after the initial infection. If malaria is suspected, it is important that the diagnosis not be discarded if parasites are not found at first; thick blood film stains may need to be repeated several times, ideally during episodes of fever. Results with thin films are unreliable for diagnostic screening, but they can be useful for determining the species of parasite when infection has been confirmed. Dipstick assays based on detection of *P. falciparum* antigens in serum are now available. The most commonly used is based on *P. falciparum* lactate dehydrogenase, which is present in blood at the time of infection but is cleared rapidly.[216] An alternative is based on *P. falciparum* histidine-rich protein 2, which persists for some time after infection.[217] A positive result with this test may be helpful in a medical emergency, but the thick blood film remains the diagnostic "gold standard."

A child with malaria may lack the classic symptoms of paroxysmal fever and body pain. The presence of vomiting, diarrhea, cough, or tachypnea can be particularly misleading. Febrile convulsions are common and need to be distinguished from the seizures that accompany cerebral malaria, the defining feature of which is coma due to *P. falciparum* from which patients cannot be aroused. Hypoglycemia sometimes contributes to the coma and must be immediately excluded. Other potential problems include severe anemia, jaundice, circulatory collapse, pulmonary edema, renal failure, and coagulation abnormalities. Vigilance is needed because, although these potentially lethal complications occur in only a minority of infections, they can arise after treatment has commenced.

The choice of antimalarial treatment depends on the species of parasite, the geographic source of infection, the age of child, and the severity of the infection. Here it is only possible to outline the general principles involved; specific recommendations should be sought from an up-to-date formulary or reference center. Oral chloroquine is generally the drug of choice for all species other than *P. falciparum*, although it is important to be aware of the increasing prevalence of chloroquine-resistant *P. vivax* in Papua New Guinea and Indonesia.[218] With *P. vivax* or *P. ovale* infection, it is also necessary to destroy the dormant liver forms with primaquine. The child's G6PD activity should be checked before administering this drug; if it is deficient, a lower dose of primaquine may be administered over a longer period. If the infective species is not known, treatment should initially be the same as for falciparum malaria because this form is the most dangerous.

Chloroquine-resistant forms of *P. falciparum* are now so widespread that chloroquine can no longer be recommended for imported infections with this species. For uncomplicated infection, several alternative treatments are available. The most convenient are combination therapies, such as proguanil with atovaquone (Malarone) or artemether with lumefantrine (Riamet). The alternative and classic method is a course of oral quinine, but this treatment needs to be followed by a course of pyrimethamine-sulfadoxine (Fansidar) if the patient is from an area where the parasites are likely to be sensitive, a course of doxycycline if the patient is older than 12 years, or a course of clindamycin.

For patients with severe malaria, the standard therapy is quinine or quinidine administered by carefully controlled intravenous infusion. The use of intravenous infusion is impractical for many pediatric wards in the tropics because of nursing shortages and inadequate infusion equipment. In this situation, quinine is commonly given intramuscularly (after being diluted to reduce the likelihood of abscess formation).[219] Artemisinin (qinghaosu) derivatives are increasingly being used because of their rapid antimalarial action.[220,221]

In areas in which malaria is endemic, the recommended treatment of uncomplicated falciparum malaria is artemisinin-based combination therapy.[222] A large multicenter study of African children with severe malaria found that those treated with parenteral artesunate had significantly lower mortality than did those treated with parenteral quinine.[223] It is therefore a matter of grave concern that *P. falciparum* is becoming increasingly resistant to artemisinin in parts of Southeast Asia, because this situation has the makings of a global health disaster if the problem spreads to Africa.[224]

The principles of intensive management for complications of *P. falciparum* infection are the same as those for any other serious systemic infection. Dextrose infusion is often required to maintain blood glucose levels, which may be suppressed by quinine or by the infection.[225] Renal function and hemoglobin levels need to be closely monitored. In a child with cerebral malaria, overt seizures are usually controlled by diazepam and phenobarbital, but subclinical seizures are common and may be highly refractory to treatment. If high doses of an anticonvulsant are necessary, it is important to recognize that the child's system is often trying to compensate for metabolic acidosis and that respiratory arrest is the most common mode of death[226]; indeed, high doses of phenobarbital have been shown to increase mortality.[227]

Fluid management of a child with severe malaria has been the focus of considerable debate recently. Studies in Kenyan children with severe malaria have concluded that overall volume status is generally low and that relatively aggressive fluid replacement may be beneficial.[208] In contrast, investigators studying Gabonese children with severe malaria found no evidence of significant hypovolemia,[228] and these authors recommend that fluid replacement regimens be relatively conservative because intracranial pressure tends to be moderately elevated.[229] A major new randomized controlled trial by Maitland and colleagues[230] showed that bolus fluid supplementation in acutely ill children resulted in an unexpected increase in 48-hour mortality in the children who were given a fluid bolus upon admission.[230] Fluids and blood transfusion should therefore be given only after appropriate and careful clinical assessment. Use of steroids does not improve the outcome for adult cerebral malaria; whether this is true for children remains unknown. No conclusive evidence indicates that any other form of adjunctive therapy is beneficial for children with cerebral malaria. Exchange transfusion is sometimes used in patients with very high parasitemia, although its efficacy has not been evaluated in a controlled trial. More effective forms of treatment of severe malaria are badly needed.

Leishmaniasis

Leishmaniasis may be contracted on short visits to countries where the condition is endemic. It is a disease that may cause considerable diagnostic difficulty when seen in the setting of a hospital in the developed world. In children with this disorder, a primary hematologic disorder such as leukemia may be misdiagnosed if the diagnosis of visceral leishmaniasis is not considered. It may be manifested as an acute disorder with fever, hepatosplenomegaly, and hemolysis or as a more chronic condition characterized by increasing hepatosplenomegaly, lymphadenopathy, and pancytopenia. The hematologic and diagnostic features were mentioned earlier in this chapter.

Treatment remains difficult, with several different drugs to chose from; all have potential toxic effects, and thus expert advice should be sought.[231-233] For many years pentavalent antimony has been the drug of choice. The preparation that is available in the United States, stibogluconate (Pentostam), is classified as an investigational drug and is obtained from the Centers for Disease Control and Prevention in Atlanta, Georgia, which provides advice on dosage schedules for particular preparations. However, significant resistance is emerging, particularly in patients with kala-azar in India, and relapses may occur even in patients who show a good response to treatment. Pentamidine has long been used as alternative for antimonial-resistant visceral leishmaniasis, but it is relatively toxic.

During the past decade we have seen the introduction of new therapies, including liposomal amphotericin, oral miltefosine, and paromomycin.[233] Although these advances are significant, they are not ideal drugs, and cheaper and less toxic therapies are still needed. Liposomal amphotericin has been shown to be at least as effective and less toxic than compounds that contain antimony for the treatment of visceral leishmaniasis, and it is now licensed in the United States for that purpose, although its high cost is a significant impediment to use in the developing world. Liposomal amphotericin has been used successfully for the treatment of visceral leishmaniasis in children.[234] Miltefosine, an alkyl phospholipid developed for use in cancer treatment, has been demonstrated to be an effective oral treatment of visceral leishmaniasis, including antimony-resistant infection.[235] A recent comparison of the different regimens for visceral leishmaniasis concluded that sodium stibogluconate is the most cost-effective option in areas with high response rates to antimonial agents; in other areas, miltefosine is most cost-effective, but its use as a first-line drug is limited by teratogenicity and the rapid development of resistance, and liposomal amphotericin remains an expensive option for poor countries where the disease is endemic.[236]

CHAPTER 39

Origins and Evolution of Pediatric Cancers

Mel Greaves

CHAPTER OUTLINE

PEDIATRIC VERSUS ADULT CANCERS
CHILDHOOD ACUTE LYMPHOBLASTIC LEUKEMIA AS A MODEL OF CLONAL EVOLUTION
EVOLUTIONARY PENETRANCE OF DISEASE
EVOLUTIONARY DYNAMICS AND CLINICAL OUTCOME

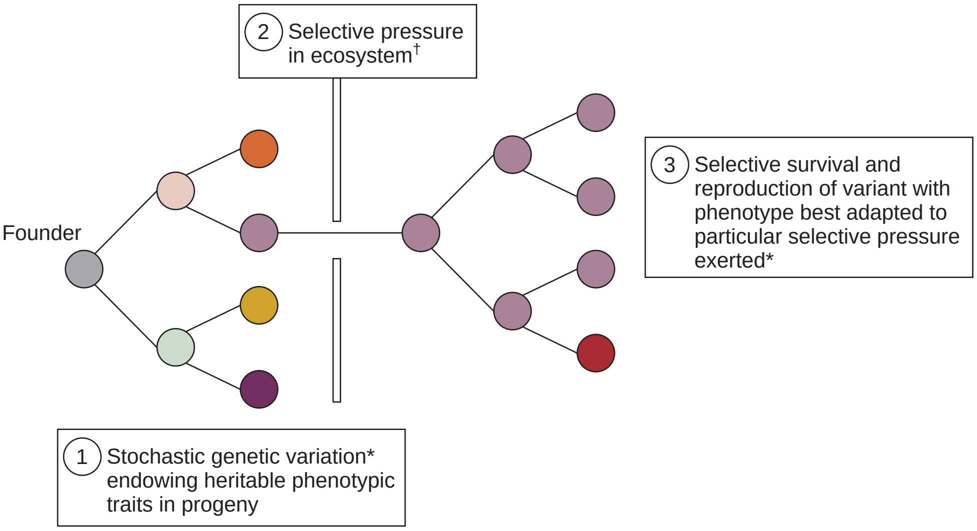
"Nothing in biology makes sense except in the light of evolution" was Dobzhansky's bold but persuasive claim, and nothing is as natural in biology as natural selection. It has been occurring for approximately 3 billion years whenever heritable traits vary in replicating populations, affecting the survival and reproductive fitness of molecules, unicellular or multicellular organisms, each in the face of environmental selective pressures.

When complex multicellular organisms evolved some 600 million years ago,[1] the potential for individual cells to be selectable, or to clone, was suppressed or rendered subservient to the fitness of the entire individual.[1] Two classic exceptions to this rule exist, however: the immune system and cancer. In the former, lymphoid cells genetically diversify their immunoglobulin heavy chain in B cells or T-cell receptor in T cells antigen recognition gene segments by recombinase-mediated rearrangement[2] to produce more than 10^{11} potentially selectable variants, collectively covering the recognition of essentially any infectious antigenic epitope. This naturally selected or adaptive system is under tight network control, although collapse of regulation can result in autoimmune disease or lymphoid cell cancers.

All pediatric and adult cancers are nonphysiologic, nonbeneficial clonal evolutions that follow the same rules of engagement as speciation in ecosystems (Fig. 39-1).[3] They are, in essence, breaking a 600-million-year-old covenant. It has been known for some time that cancer is a paradigmatic Darwinian, adaptive system.[4] The implications for cancer risk, progression of disease, prognosis, drug resistance, and clinical response have only more recently been appreciated.[3,5,6] Genomics has contributed significantly to this sharpness of focus,[7] just as it has reinforced the underlying principles of evolutionary phylogeny and natural selection of species and variants.[8,9] As in speciation, what emerges in cancer in terms of functionally important mutations (the so-called *drivers*) or subclones is the consequence of selective pressures exercised via the tissue habitat or ecosystem (Fig. 39-2), with outcome being heavily modulated both by variation in inherited susceptibility and by chance. Inherited susceptibility is a marked feature of pediatric cancers, both in terms of familial syndromes and in sporadic cases with little or no family history, as revealed by genomewide association studies.[10-13] The element of chance applies in both cancer and evolution in general because mutations arise throughout the genome in a stochastic manner and independently of the functions encoded by particular genes.[14] For mutations to have a functional impact in cancer requires that they occur in a manner that alters protein function (and consequently cell fitness) and in the appropriate context with respect to cell type and the presence (or absence) of other mutations with which they may be epistatic or interactive. The vast majority of mutations are neutral passengers of no consequence. The mutations we see recurrently are the result of natural or therapeutic selection.

As clones evolve over time (within a few years for most pediatric cancers compared with decades for adult carcinomas) they also move in space or throughout tissue ecosystems, both within the primary site and to secondary sites.[15,16] This characteristic has important implications for biopsy-based sampling, because anything other than the complete tumor will be a biased selection of subclones.[3] This phenomenon has been well documented for adult cancers, and we assume that the same phenomenon must apply to most if not all pediatric solid tumors.

In evolutionary or Darwinian selection, it is the phenotype that is the focus of selectability—for example, a predator with sharp teeth, a thermoresistant bacteria, or a drug-resistant bacterium or cell. In addition, stable phenotypes are initiated and sustained by genotypic



2 Selective pressure in ecosystem†
Founder
3 Selective survival and reproduction of variant with phenotype best adapted to particular selective pressure exerted*
1 Stochastic genetic variation* endowing heritable phenotypic traits in progeny

Figure 39-1 Principles of evolution by natural selection. *Different colored circles* represent genetic variants. If selection is stringent, there may be a selective sweep (winner takes all), as shown in the figure, with one or a few individuals surviving. A selective sweep may occur in key junctures in the evolution of cancer—for example, with in situ carcinoma to invasive cancer transition in adults, with metastases (which are usually monoclonal), and with the emergence of drug-resistant mutants in postchemotherapy relapse or recurrence. However, note that winners can become losers if the selective conditions change; as George Williams noted, "Evolution has no eyes to the future." *Must be present in germ cells for sexually reproducing multicellular organism selection, or, in cancer, in self-renewing stem cells.[22] †A wide variety of selective pressures exist in a diverse ecosystem, including interspecies competition for limited resources (food or mates), predation, and climatic factors.

alterations that are either mutational or epigenetic. However, any evolutionary system must have a "unit of selection," which is defined classically as any unit that replicates and in which a stable phenotype is linked to survival and/or reproductive success.[17] For bacteria and protists, this unit is the single cell. For multicellular organisms, it is the entire individual.[1] For cancer it will be somatic cells but probably not every cancer cell. The key attribute of any unit of selection is extensive replicative potential plus expression of the selectable phenotype. Extensive replication capacity, or self-renewal, is the key and exclusive feature of cancer stem cells.[18] The numbers of stem cells vary greatly in individual cancers and are generally increased in frequency with progression of disease and clinical malignancy.[19] In addition, the stem cell state may not be entirely stable, and under some circumstances (microenvironmental or mutational), non–stem cell progenitors can acquire or reacquire stem cell status.[20,21] Despite these variables, it is likely that cancer stem cells are the units of selection that drive and sustain the evolution of cancer clones and are the repositories of drug resistance.[22]

PEDIATRIC VERSUS ADULT CANCERS

All cancers are consequences of stable variation in somatic cells that facilitate clonal escape.[23] However, fundamental differences exist between pediatric and adult cancers

TABLE 39-1 Differences Between Pediatric and Adult Cancers

Variable	Pediatric	Adult
Predominant lineage origins	Transient/ developmental tissue progenitors in embryo and fetus Fetal blood	Epithelia Adult blood
Time frame of natural history	Months to 15 yr	2-3 decades
Number of "driver" mutations required	2 (?)	5-8 (?)
Genetic instability	Rare	Common
Major risk factors	Endogenous proliferative stress (?)	Genotoxic exposures, persistent proliferative stress (hormonal), or infection
Cumulative risk	~1 in 800 (0-15 yr)	~1 in 3 (16-90 yr)
Age-associated incidence distribution	Defined, age-linked peak incidence in infancy or childhood	Increases as power of age*

*Some exceptions are testicular cancer and Hodgkin lymphoma in young adults and choriocarcinoma.

(Table 39-1). The most striking of these differences is the context of tissue or cell type involved, which in turn can be rationalized in terms of underlying risk factors. Most adult cancers are the consequences of protracted environmental or lifestyle exposures to epithelia.[24] In contrast, most pediatric cancers can best be viewed as developmental accidents arising during very restricted windows of tissue morphogenesis in the embryo or fetus when particular stem or progenitor cells are proliferating.[25-27] This view is supported by the finding that many of the inherited gene variants that contribute to the risk of pediatric cancer[11,13] and many of the somatic mutations that are restricted to the cancer cells themselves[28] are encoded by genes that are critical for the normal developmental biology and differentiation of the cells involved. Very few pediatric cancers are attributable to any known in utero external exposure (i.e., via the pregnant mother), despite an epidemiologic quest to find them lasting decades. This is not to say that pediatric cancers are not subject to variable risk factors. Aside from inherited variation in susceptibility, the numbers of cells at risk and proliferative stress may play a part. Higher birth weight is consistently associated with excess risk of pediatric cancer[29] and may operate by simply increasing the number of proliferating "target" cells at risk. Patterns or timing of infection (especially in affluent, "hygienic" societies) may promote or trigger the clinical development of childhood B-cell precursor acute lymphoblastic leukemia (ALL).[30] This mechanism is likely to operate via proliferative stress on preleukemic clones that are generated in utero (rather than via specific viral transformation).[30] Similarly, the striking peak of incidence of long bone osteosarcoma in adolescents might reflect the clinical emergence of a cancer initiated long before (prenatally) but promoted by the proliferative stress of the long bone growth spurt associated with puberty.[31]

A few types of cancer occur in both children and ageing adults, with acute leukemias and gliomas being clear examples. However, it is interesting that the genetics or mutational spectrum of these cancers,[32] and probably their etiology, is very different according to age. Two nonexclusive "seed or soil" interpretations of this distinction have been proposed. One interpretation is that the mutations are different because the microenvironments and selective pressures are different, resulting in different mutant genes providing clonal advantage. A second interpretation is that the mutations are cell context–sensitive and that the cell type of origin is different and developmentally constrained. Evidence for the latter interpretation came from mouse modeling of the impact of *GATA1* mutations, which revealed that the cellular targets that, with this mutation, lead to acute megakaryocytic leukemia in infants with Down syndrome, are developmentally restricted to the yolk sac and fetal liver.[33]

The tissue distribution, composite phenotypes (or cell type), and gene expression profiles of pediatric cancers provide a strong indication of the possible lineage and cell type or origin,[34-38] and this indication is endorsed by animal models (Table 39-2).[39-41] Subtypes of some cancers, such as medulloblastoma, may have distinct developmental origins.[42] No unambiguous way exists to identify precisely when and where any childhood cancer is initiated by somatic mutations. Most mutations are assumed to originate prenatally either in the embryo or the developing fetus, possibly when the cell lineage stem or progenitor cell "targets" are under maximum risk from proliferation.[43]

CHILDHOOD ALL AS A MODEL OF CLONAL EVOLUTION

Childhood leukemias lend themselves to interrogation of their natural history more than any other pediatric cancer type. This situation occurs because, although it is initiated in tissue sites such as fetal liver, bone marrow, or thymus, the clone disseminates very readily into the accessible blood, including in the early stages of clinical covert natural history, such as at the birth of the child. Figure 39-3 illustrates a minimal two-stage model proposed for the development of the common form of B-cell precursor ALL in children.[30,44] The challenge was to backtrack clonal history from the point of diagnosis when the genetic features of the clone were definable. For this task, chromosome translocation–generated chimeric gene fusion sequences are the ideal markers for clonal tracking, as illustrated in Figure 39-4 for the most frequent of such fusion genes, ETV6-RUNX1 (formerly TEL-AML1).[45,46] Three tactics have been successfully adopted for backtracking clonal history in ALL (Fig. 39-5),[44,47] and collectively they have provided persuasive evidence for the in utero origin of disease and the two-step model that has been proposed. Formal proof of a prenatal origin of other

pediatric cancers is not available, although the very young age of many patients at diagnosis and the embryonal phenotypes of some make a prenatal origin very likely.[43] The oldest age at diagnosis of ALL to date with backtracking evidence for an in utero origin is 14 years.[48] However, it is possible that some leukemias and other tumors in older children and even young adults are initiated prenatally with a protracted clinically silent latent period—for example, osteosarcoma in teenagers and testicular cancer in adults in their twenties and thirties.[37] This scenario has yet to be formally assessed, however.

Monozygotic twins with concordant or discordant clinical ALL have been especially informative in defining the sequence of prenatal and later secondary but essential genetic hits (Fig. 39-6, *A* and *B*).[47,49,50,51] These data strongly suggest that fusion genes (or hyperdiploidy) are common initiating, prenatal genetic events in childhood ALL. This suggestion is supported by modeling experiments with murine and human blood cells, which indicate that *ETV6-RUNX1* can initiate a preleukemic phenotype but that additional genetic changes are required for progression of disease and overt clinical ALL.[52,53] When coupled with in-depth second-generation, whole-genome sequencing, it becomes possible to define the genetic landscape of ALL as assembled via the two independent prenatal and postnatal steps (Fig. 39-7).

This explanation still leaves unclear how the "set" of secondary abnormalities (copy number alterations and single nucleotide variants) are accrued; that is, are they sequentially acquired, and if so, does this acquisition occur in any preferential order or as some type of bolus? This question has been resolved by single-cell genetic analysis and inferred clonal phylogeny (Fig. 39-8).[54,55] The striking—although, from an evolutionary perspective, not

surprising—result is the branching clonal architecture, which is now seen as a hallmark feature of cancer,[3,7] just as it is seen as a hallmark feature of biological speciation and evolution in general (Fig. 39-9). Relapse can originate from within either major or minor subclones that are present at diagnosis[54,56] and can involve positive selection of prior, very rare subclones with mutations that render these cells resistant to particular drug therapies.[57] An implication of these data is that a patient with ALL (and other pediatric cancers) has multiple subclones with malignant potential. This implication in turn implies that distinct subclones should be generated and sustained by genetically distinct (and diverse) self-renewing stem cells. This situation has been shown to be the case for ALL by comparing single-cell genetics and clonal phylogenies of diagnostic samples with those generated by serial transplantation in NOD/SCID-IL2R$\gamma^{-/-}$ (NSG) mice.[54] Stem cells are the "units of selection" in the evolutionary development of cancer,[22] and as such their genetic diversity and plasticity of phenotype (including quiescence option) is a key or even possibly the key parameter in clinical outcome.

Figure 39-8 Inferred clonal architecture and phylogenetic tree in acute lymphoblastic leukemia (ALL). B1, Normal cells; B2-7, ALL subclones with individual genotypes listed alongside with the percentage representation in the entire population. B3 at 54.0% is the dominant subclone. Mutations listed were determined by whole exome sequencing (depth 100×). Deoxyribonucleic acid copy number alterations were determined by single nucleotide polymorphism array.[55] Single cells were flow sorted and genotyped by multiplex quantitative polymerase chain reaction using the Fluidigm BioMark microfluidic platform (Fluidigm, South San Francisco, Calif.). Maximum parsimony (PAUP) was the method used for assembling the phylogenic tree and the software that was used. *(From Potter N, Ermini L, Papaemmanuil E, et al: Single cell mutational profiling and clonal phylogeny in cancer.* Genome Res *23:2115–2125, 2013.)*

Another marked feature of ALL clonal architecture and its genetic variegation is the finding that the same gene is frequently altered, or mutated, independently in distinct subclones (or phylogenetic branches) of ALL in individual patients.[54,58] Reiterated gene mutation is seen in some other leukemias and solid tumors[16] and presumably reflects strong selection for particular gene alterations that have an impact on cell fitness. Additionally, however, some mutations may not be entirely stochastic or random. Bioinformatic scrutiny of *ETV6-RUNX1*–positive ALL genomes have revealed that half or more of all recurrent copy number alterations, mostly deletions, have lymphoid recombinase, *RAG1/RAG2* recognition motif heptamer nonamer sequences close to the break points.[59] Recombination-activating genes are expressed constitutively in normal B- and T-cell precursors as part of the physiologic program of immunoglobulin heavy chain and T-cell receptor gene rearrangement.[60] These enzymes continue to be expressed in ALL, where they may saturate their physiologic targets and mutate other substrates.

EVOLUTIONARY PENETRANCE OF DISEASE

Pediatric cancers are rare in human and animal species. Were they not, their highly deleterious impact on reproductive fitness (prior to the advent of successful therapy) would have led, by natural selection, to more potent suppressive mechanisms. The evolution of complex multicellular organisms required the elaboration of suppressor gene functions[31,61] to ensure cohesion and integration of diverse cell functions. That this mechanism so clearly fails in ageing adult humans is, we assume, a reflection of the weak impact of natural selection postreproductively and the chronic exposure patterns associated with human societies that can overwhelm suppression.[14]

It might then be assumed that the 1 in 800 risk of childhood cancer is a compound of the various components of risk (Fig. 39-2). However, it is well recognized that the evolutionary progression of adult cancers is both sluggish and inefficient because substantially more covert, early or premalignant lesions (e.g., carcinomas in situ) exist than ever emerge as a clinical malignancy.[62] This situation

Figure 39-9 Branching phylogeny in speciation as depicted by Charles Darwin in his 1837 notebook. Founder individual 1 gives rise via a branching architecture to descendents A, B, C, and D.

raises an interesting question with regard to pediatric cancer: how often is the disease initiated prenatally but then stalls or regresses and fails to evolve to overt cancer? Presumably more frequently than 1 in 800 instances? An answer to this question has been determined for ALL using a tactic available for bloodborne premalignant cells. Careful molecular screening of a large series (approximately 600) of unrelated cord blood samples revealed that expanded clones of *ETV6-RUNX1*–positive B lineage cells were present at some 100 times the rate of clinical ALL with the same fusion gene (Fig. 39-10).[63]

Is this result peculiar to childhood leukemia? Probably not. Autopsy histopathologic data suggest a similar approximately 100-fold incidence of the premalignant lesions for neuroblastoma[64] and Wilms tumor[65] (resulting in approximately a 1% incidence in newborns). This finding presumably reflects a low probability of the acquisition of necessary secondary genetic events. This low penetrance could be due to a limited life span of the premalignant clone, an absence of the required promotional impact of postnatal proliferative stress, altered microenvironmental selective pressures, or an influence of inherent genetic susceptibility.

EVOLUTIONARY DYNAMICS AND CLINICAL OUTCOME

The clonal dynamics of cancer are extremely variable, but the time frame to overt malignancy for most pediatric cancers is measured in a few years versus a few decades in adults. As in ecologic speciation,[66] the pace of evolution is not constant or steady; periods of stasis or slow, parallel clonal evolution and codominance (or even regression) are occasionally punctuated by major selective sweeps where, in cancer, one subclone emerges to dominance. Genetic analysis of both adult[67] and pediatric cancers[68] suggests that these key transition times in clonal evolution occur when in situ tumors become diffuse, with metastases and posttherapeutic recurrence or relapse. These changes reflect the imposition of stringent selective pressures.

In contrast with the common adult carcinomas, a striking feature of pediatric cancers is the low mutational burden.[69] Most pediatric cancers have around 10 nonsynonymous exomic nucleotide alterations compared with

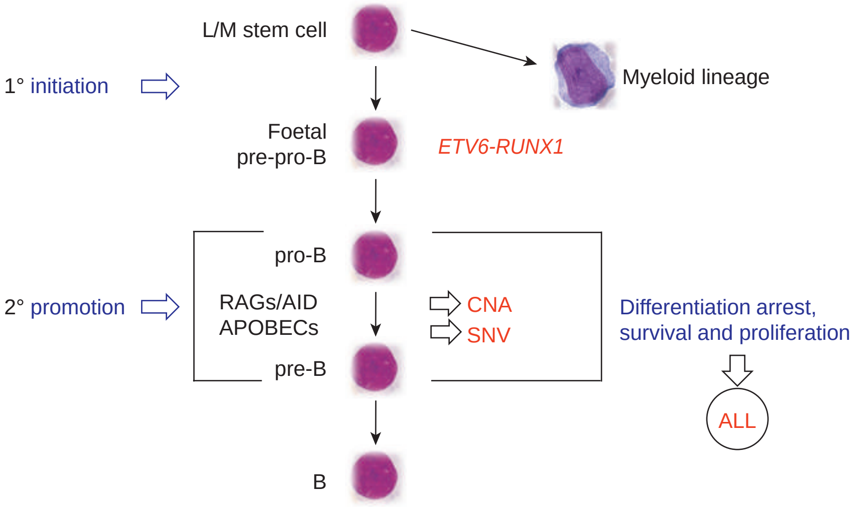

Figure 39-11 Developmental model for childhood B-cell precursor acute lymphoblastic leukemia (ALL). Lymphomyeloid (L/M) stem/progenitor cells. The model shows preleukemic ALL clones initiated (by gene fusion or hyperdiploidy) in the fetal, early pre-pro-B stage. An overt ALL clone with secondary genetic changes (copy number alterations [CNA]/single nucleotide variants [SNV]) becomes trapped in differentiation arrest. Off-target RAG1/RAG2 recombinase activity (R) generates reiterated and highly recurrent CNA. APOBEC enzymes induce SNV.[59]

50 to 70 for many adult cancers and several thousand for the adult cancers associated with known genotoxic exposures (e.g., lung cancer and melanoma).[69] Part of this distinction can be attributed to the frequent presence of genetic instability in many adult cancers, which itself is a possible adaptive cellular response to genotoxic exposure.[70] However, it is also possible that within the architectural constraints of a structured epithelium, more restraints on cancerous growth must be abrogated by mutations. The minimal number of mutations necessary for the evolution of malignant pediatric cancer is difficult to determine, but it could be as few as two or even one for rare pediatric cancers in which the initiating genetic lesion is a major chromatin modifier with pleiotropic impact on multiple pathways, such as *MLL-AF4* fusion in infant ALL[71] and *SMARCB1* in rhabdoid cancer.[72] Two mutations might be sufficient for most pediatric cancers if these mutations effectively uncoupled proliferation from differentiation and if, in the developmental context, this uncoupling caused relatively rapid onset of a diagnosable disease, leading to relatively early detection of these cancers in their evolutionary trajectory.

These considerations may be relevant to the success in treatment of pediatric cancer. Prior to the advent of combination chemotherapy, all cases of childhood ALL were universally fatal within around 12 months.[73] The current long-term remission and possible cure rate for *ETV6-RUNX1*+ ALL is close to 100%.[74] Other rarer subtypes of ALL are considerably more intransigent.[75] What is it about the evolutionary biology of the major, or common, subtypes of pediatric ALL that render them curable with use of relatively generic cytotoxics? In adult cancers, evidence indicates that the extent of clonal, genetic diversity is a strong predictor of progression of disease[76] or eventual clinical outcome.[77] One interpretation of this situation is that genetic diversity is fueled by genetic instability and high diversity, which substantially increases the likelihood of acquisition of drug-resistant mutations. Minimal genetic diversity arising at the time of "early" diagnosis may therefore be critical to the curability of *ETV6-RUNX1*+ ALL. However, other factors probably also contribute, including an origin from a progenitor (B) population that is intrinsically very sensitive to deoxyribonucleic acid (DNA) damage and apoptosis.[78] The same dynamic may apply to embryonic progenitors that give rise to other pediatric cancers that are intrinsically sensitive to radiation and chemotherapy.[25] In addition to mutation rate or load, the particular mutations selected may also be crucial. Adult cancers with genetic instability have a very high frequency of *TP53* mutations or deletions,[79] which may reflect an adaptive cellular response to DNA damage; the downside is resistance to chemotherapy. *TP53* mutations are rarer in pediatric cancer and absent from *ETV6-RUNX1*$^+$ ALL.[59] Also missing from curable *ETV6-RUNX1*$^+$ ALL are kinase mutations[59] that are a hallmark feature of high-risk childhood ALL.[75] Although deletions of the cell cycle inhibitor *CDKN2A* (*p16*) are very common in all ALL (and other pediatric cancers), the lack of proliferative "driver" oncogene mutations (i.e., activated kinases) is striking. This finding supports the notion that the common variants of childhood ALL and possibly several other types of pediatric cancer, including Wilms and germ cell tumors, are in effect minimally modified, albeit expanded, clones in differentiation arrest and that this status renders them chemosensitive (Fig. 39-11).

Congenital Anomalies
Birth Weight and Length at Birth
Vitamin K
FUTURE DIRECTIONS

Leukemias of childhood are a highly heterogeneous group of diseases. In reviewing the descriptive and analytic epidemiology of these malignancies, we have, when possible, emphasized specific subgroups as defined by morphologic, cytogenetic, or molecular features. In selected instances, evidence indicates that specific subgroups of leukemia may have distinct causes and that molecular abnormalities associated with particular subgroups may be linked with specific causal mechanisms. In assessing risk factors, studies of the childhood leukemias present several methodologic advantages compared with those addressing adult leukemias. For example, because the interval between exposure to putative risk factors and the onset of leukemia is shorter, recall of exposures is likely to be more accurate and intervening factors are less likely to be of importance than are those associated with adult leukemias. These characteristics of childhood leukemia better lend themselves to an approach that includes both population studies and molecular epidemiologic techniques, permitting the design of studies to assess interactions between genes and the environment. However, in striking contrast to the impressive advances in the treatment and biology of childhood leukemia, remarkably little has been achieved regarding our understanding of the cause of leukemia, the most common form of childhood malignancy.

DESCRIPTIVE EPIDEMIOLOGY

Leukemias are the most common cancers affecting children, accounting for 32% of all occurrences of cancer among children younger than 15 years and 27% of occurrences of cancer among children younger than 20 years.[1] Each year in the United States, leukemia is diagnosed in approximately 3540 children who are younger than 20 years. Of these occurrences, acute lymphoblastic leukemia (ALL) accounts for 73%, acute myeloid leukemia (AML) accounts for approximately 18%, and chronic myeloid leukemia (CML) is rarely seen, accounting for less than 4%.

International Patterns

A wide variation exists in the incidence of childhood leukemia by geographic location. The highest annual incidence rates are reported in Costa Rica, Ecuador, Hong Kong, Denmark, and Singapore (57.9 to 51.0 per million population), whereas some of the lowest rates are found in Zimbabwe, India, Israel, and Algeria (23.1 to 26.0 per million).[1] The annual incidence of childhood leukemia for many regions, including North America, Australia, Northern and Western Europe, China, Japan, the Philippines, and Singapore, ranges between 35 and 50 per million (Table 40-1). When evaluating geographic variation in disease incidence, concerns always exist regarding the quality and completeness of reporting. Ecologic studies of childhood leukemia incidence according to annual per-capita gross national income demonstrates substantial variation within low-income countries and a much narrower range in middle- and high-income countries.[2] In addition, a significant correlation exists between the incidence of childhood leukemia and population mortality rates for children younger than 5 years in low- and middle-income countries. Some of the lowest reported childhood leukemia rates are within countries with high mortality rates for children younger than 5 years, suggesting that children with undiagnosed leukemia may die in some low-income countries as a result of anemia or fever that is attributed to infectious disease.

Age-Specific Incidence and Sex Ratio

The incidence rate for all leukemias is highest among children younger than 5 years and decreases with age.[3] The age-adjusted incidence for boys exceeds that for girls, with a sex ratio typically between 1.1:1 and 1.4:1.[1]

TABLE 40-1 Incidence of all Childhood Leukemias, ALL, and AML in Selected International Sites

	ANNUAL INCIDENCE RATE (PER MILLION POPULATION)*		
Country	**Leukemia**	**ALL**	**AML**
Costa Rica	57.9	46.3	8.9
Ecuador	56.3	39.6	9.1
Hong Kong	53.9	40.6	3.9
Denmark	53.0	42.8	8.4
Singapore	51.0	39.5	6.9
Canada	50.8	41.0	6.3
Finland	49.9	41.9	5.4
Australia	49.9	39.9	8.0
Italy	49.1	37.9	7.9
Sweden	48.7	40.1	6.7
Norway	48.6	38.3	8.0
Philippines	48.1	25.2	8.6
United States (white)	46.9	38.0	6.0
Germany	46.6	39.0	6.7
Uruguay	44.0	29.3	7.4
Colombia	42.8	31.5	6.4
United Kingdom	40.8	32.8	6.3
France	40.5	31.7	6.1
China	40.3	17.4	6.7
Netherlands	40.1	30.9	5.8
Japan	38.5	22.6	7.2
Korea	38.1	20.2	8.7
Cuba	37.7	25.4	5.7
Czech Republic	37.1	28.4	5.1
India (Delhi)	36.0	23.1	6.1
Peru	35.9	25.4	6.9
Brazil	33.7	21.9	5.3
Thailand	29.8	19.8	5.8
United States (black)	29.4	20.8	6.2
Algeria	26.0	14.3	5.7
Israel	25.7	18.6	5.3
India (Bombay)	25.4	16.0	4.8
Zimbabwe	23.1	11.6	11.0

Data from Parkin DM, Kramárová PE, Draper GJ, et al, editors: International incidence of childhood cancer, *vol II (IARC Scientific Publications No. 144). Lyon, France, 1998, International Agency for Research on Cancer.*

ALL, Acute lymphocytic leukemia; *AML,* acute myeloid leukemia.

*Children 0 to 14 years of age.

Acute Lymphoblastic Leukemia

In developed countries, the age-incidence curve for ALL is characterized by a peak between the ages of 1 and 4 years (Fig. 40-1).[4] Thus a sharp peak in ALL incidence is seen among 2- to 3-year-olds (>100 per million), which decreases to a rate of 20 per million for 8- to 10-year-olds. The incidence of ALL among 2- to 3-year-olds is approximately fourfold greater than that for infants and is nearly tenfold greater than that for 19-year-olds. Although this age distribution is well recognized and attributable to common ALL (cALL),[5] it has not always been present. It was first observed in England and Wales in the 1920s,[6] among American whites in the 1940s,[6] among African Americans[7] and in Japan in the 1960s,[8,9] and among Jews and non-Jews in Israel in the 1970s.[10] In Kuwait, where the incidence was low during the 1970s, the age peak has recently been observed, whereas in the African series, in which the incidence is also low, the peak has not yet been reported.[11]

An exaggerated peak incidence among 2- to 3-year-olds, with a very low incidence of ALL in older children, was observed in certain areas of England and Wales and in the rural north of Scotland and coincided with a high socioeconomic status. These observations have led to a hypothesis that an elevated risk of ALL is influenced by community characteristics such as isolation, high socioeconomic status, and population mixing,[12] which in turn are related to immunologic isolation in infancy and influence patterns of exposure to common infectious agents in the early years of life before the appearance of leukemia.[13] These hypotheses are discussed in detail later. The ratio of incidence rates of ALL for boys and girls ranges between 1.1 : 1 and 1.3 : 1.[11]

Acute Myeloid Leukemia

Among children, the incidence rates for AML are highest in infancy and are fairly uniform in older children (see Fig. 40-1).[4] In the United States, during 1986 to 1995, the incidence in the 0- to 4-year-old age group was 10.3 per million, and in the 5- to 9-year-old and 10- to 14-year-old groups it was 5.0 per million and 6.2 per million, respectively. Comparable rates have been reported elsewhere in Europe and in England. The male-to-female ratio is close to unity for AML.[1]

Chronic Myeloid Leukemia

The incidence rates of CML in one of the largest series, originating from the United Kingdom, were 1.2 per million for infants and 1.6, 0.5, and 0.7 for children aged 1 to 4 years, 5 to 9 years, and 10 to 14 years, respectively,[14] which are comparable to rates observed in the United States for these age ranges.[4] The rate for CML increases during the 15- to 19-year age interval. The male-to-female sex ratio is 1.6 : 1.[1]

Myelodysplastic Syndrome and Other Myeloproliferative Diseases

The International Classification of Childhood Cancer[15] includes a classification for myelodysplastic syndrome (MDS) and other myeloproliferative diseases. In the 0- to 19-year age group, rates for MDS are very similar to those for CML; however, in contrast, the incidence of MDS is highest among infants and drops essentially to 0 by age 8 years.[4] The incidence is almost twice as high among males.

Ethnic Origin

In the United States, substantial variation is seen in the incidence rates of ALL by ethnicity. The highest rates are reported among Hispanics, Filipinos, and Chinese, and the lowest rates are reported among African Americans.[4] The incidence rates among whites are moderate to high by international standards, whereas those for American Indians are somewhat lower.

On the other hand, two studies have investigated the incidence of childhood cancer by ethnicity in England, but results were negative. The lack of variation in the incidence of ALL among ethnic groups in England, in conjunction with the markedly lower incidence of ALL in the Indian subcontinent and Africa than in England, suggests that the incidence of ALL depends to some extent on environmental factors in association with geographic location. The contrast between the ethnic variations in incidence could be a reflection of the socioeconomic differences by ethnicity (or the lack thereof) in the two countries.[14] A recent report from the Malaysia-Singapore Leukemia Study Group describes differences in prognostically important chromosomal abnormalities among an unselected multiethnic Asian population.[16] Ethnic groups differed significantly with regard to the proportion of patients with ALL who had T-cell ALL (the incidence is higher in Chinese and Indians), *ETV6-RUNX1* (with a lower incidence in Chinese persons), and *BCR-ABL* (with a lower incidence in Indian persons). Beyond ethnic differences in the occurrence of childhood ALL, it has been well documented that race/ethnicity is associated with prognosis.[17] The black-to-white ratio of the incidence of AML in the United States is 0.85. The rates are highest among Hispanics.[1,18] This higher rate of AML contributed to the higher incidence of acute promyelocytic leukemia seen among Hispanics than among non-Hispanics, thus raising the question of genetic predisposition to acute promyelocytic leukemia or exposure to distinct environmental factors.[19] As with ALL, race/ethnicity also has prognostic importance.[20]

Socioeconomic Status

Socioeconomic factors have been proposed as an explanation for the age peak in childhood leukemia.[21] Thus it has been hypothesized that with economic development, poorer communities move from a situation in which leukemia is rare (T-cell ALL is the predominant type of ALL) through an intermediate stage in which cALL begins to appear to a state of high socioeconomic status that is associated with a high incidence of ALL and cALL. Numerous descriptive studies have investigated the relationship between leukemia and socioeconomic status.[22-28] In the vast majority of these studies, the area of residence of the patients (or those who died) was used as a measure of socioeconomic status. Other measures used included household income and years of schooling. In most of

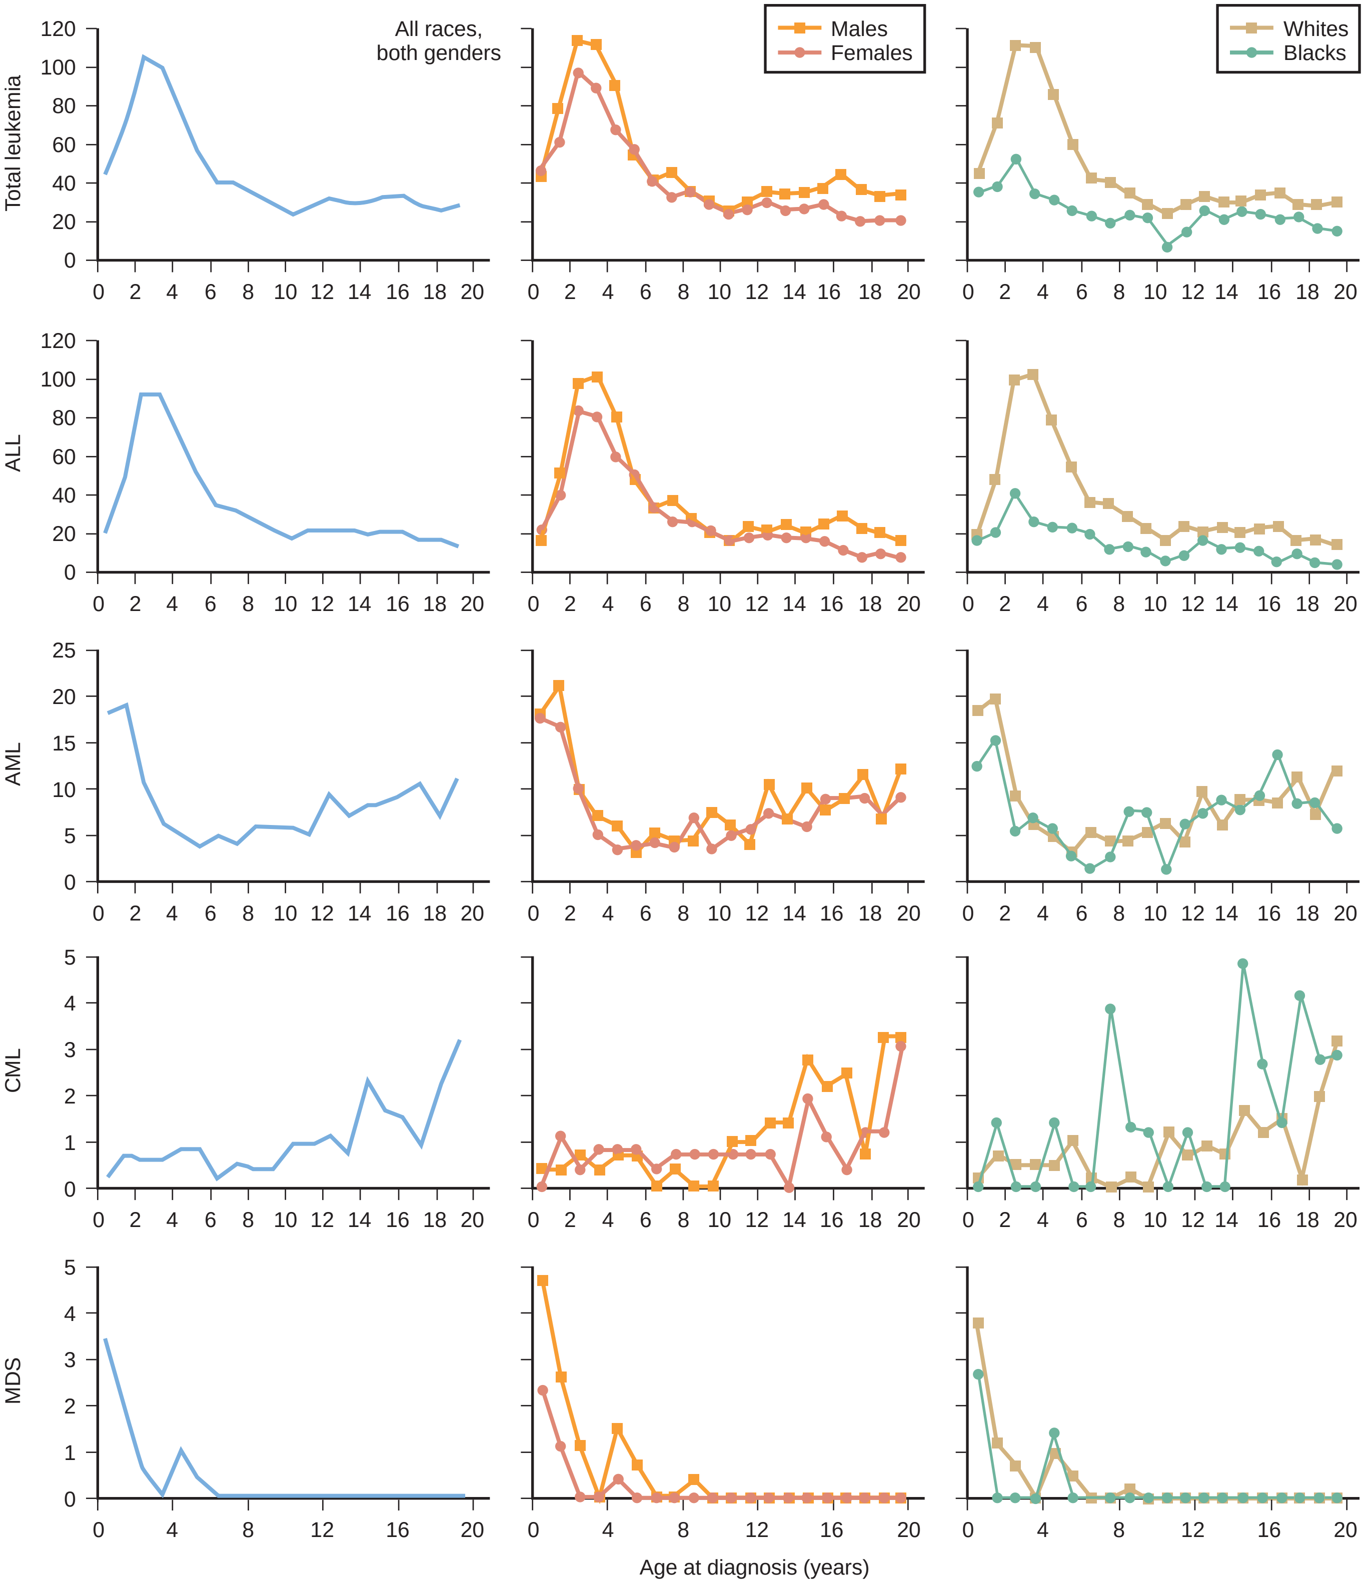

Figure 40-1 Incidence of leukemia (per million children) by age at diagnosis. *ALL,* Acute lymphoblastic leukemia; *AML,* acute myeloid leukemia; *CML,* chronic myeloid leukemia; *MDS,* myelodysplastic syndrome.

these studies, a weak positive association between leukemia and high socioeconomic status was observed, with a few exceptions.[24,27,29-31] In contrast, several investigators have examined the relationship between AML and socioeconomic status and have failed to show an association.[23]

Time Trends

Several investigators have examined temporal trends for leukemia, but the findings are difficult to interpret,[32-37] primarily because of the varying periods covered and different methods of analysis used. Some investigators analyzed the 0- to 14-year-old age group as a whole, whereas others examined trends in specific age groups. Some investigators reported trends for each sex, whereas others combined the two sexes in their analyses. In some analyses all leukemias were grouped together, whereas others conducted their analyses by the leukemia subtype. In addition, diagnostic improvements have led to more accurate and precise classification of leukemias over time, which could contribute to the observed temporal trends in incidence.

In the studies reporting an increase in the incidence of ALL, the increase is fairly modest and is confined to the 0- to 4-year-old age group. Moreover, in some reports, the increase in incidence of ALL appeared to be accompanied by a decrease in the incidence of AML or other leukemias, which could reflect diagnostic shifts and more accurate and precise classification.[38-40] A temporal increase in the incidence of childhood ALL has been reported in England[41] and is attributed to an increase in the precursor B-cell subtype.[42] Between 1974 and 2000, the average annual increase in childhood ALL was 0.7% overall but 1.4% for cALL. Similarly, analyses of childhood ALL time trends in Italy demonstrated increases, some of which were related to maternal time variables that included maternal age and maternal birth cohort, which were considered to be consistent with an infectious cause.[43,44] On the other hand, in another study, Linet and associates[45] report no substantial change in the incidence of childhood leukemia diagnosed in the United States between 1975 and 1995. The Czech national registries reported a 1.5-fold increase in childhood ALL incidence between the ages of 1 to 4 years during the period of substantial socioeconomic transition in the European postcommunist countries.[46]

Clustering of Leukemia in Space and Time

Spatial clustering of childhood leukemia has been observed to varying degrees in England,[47,48] France,[49] and Greece[50] but not in the United States.[51-55] Where spacial clustering was identified, it was strongest for leukemias diagnosed in younger children. Although spatial clustering was confined to sparsely populated areas in England, such clustering was found only in urban areas in Greece. Birch and colleagues[56] addressed the issue of space-time clustering by using the Manchester Children's Tumor Registry. All methods showed highly significant evidence of space-time clustering on the basis of place of birth and time of diagnosis of childhood leukemia. The authors concluded that the results were consistent with an infection hypothesis (discussed later). Furthermore, the investigators found an excess of instances in males versus females in space-time pairs, thus suggesting gender-specific susceptibility to infections. More recently they have reported statistically significant cross-clustering among childhood leukemia and central nervous system (CNS) tumors and between ALL and astrocytoma, suggesting possible common causes, possibly of an infectious nature.[57] The correlation between childhood leukemias and CNS tumors is of interest, given the recently reported correlation in international rates for these two pediatric cancers.[58]

Historically, clusters of childhood leukemia have been observed in which the number of cases reported exceed those expected within a given time and geographic location. Investigation of these clusters has typically not identified any causal agent. A recent leukemia cluster in the United States gained substantial public and scientific attention because of the marked excess observed within a small population.[59] Comprehensive investigation including biologic samples from persons within the population that were analyzed for chemicals, viral markers, and genetic polymorphisms, in conjunction with air, water, soil, and dust sampling, failed to identify any leukemia risk factor.[60]

GENETIC FACTORS AND FAMILIAL AGGREGATION

Certain genetic syndromes are associated with an increased susceptibility to leukemia.[61] These syndromes include Down syndrome,[62] neurofibromatosis type 1,[63] and chromosome breakage syndromes, such as ataxia telangiectasia,[64] Bloom syndrome,[65] Shwachman syndrome,[66,67] Fanconi anemia, and Langerhans cell histiocytosis.[68] Shaw and associates[69] reported an association between Klinefelter syndrome and childhood leukemia on the basis of an observation of two children with ALL who had a 47XXY karyotype. However, Hasle and colleagues[70] subsequently reported no increase in the incidence of childhood leukemia in a cohort of 696 men with Klinefelter syndrome. In a recent study of malformation syndromes among children with cancer, an association was reported between Bardet-Biedl syndrome and ALL.[71]

Although specific associations have been described mainly as case reports, data on the proportion of instances of leukemia that are known to have a genetic etiology or are associated with specific genetic syndromes are limited. In a study from England, 2.6% of children with leukemia were reported to have a recognized genetic condition, and this percentage was almost entirely accounted for by Down syndrome (2.3% of all leukemias).[72] This proportion is similar to that found in studies from the United States and Nordic countries.[73-75]

Population-based studies using record-linkage approaches have documented that approximately 97% of cancers occurring among children with Down syndrome are leukemia.[76] Persons with Down syndrome have an estimated 56-fold increase in leukemia between the ages of 0 to 4 years, which declines to tenfold for leukemia risk between the ages of 5 to 29 years. More recently, interest has been increasing in the identification of environmental factors that may contribute to the development of leukemia among patients with Down syndrome.[77] Case-control investigations comparing persons with Down syndrome who have leukemia with persons with Down syndrome who do not have leukemia have found that reduced risk of leukemia is associated with maternal vitamin supplementation in the periconceptional period and reported history of infection in the first 2 years of life.[78,79]

Concordance of Childhood Leukemia in Twins

Assessment of concordance for childhood leukemia in twins may provide etiologic clues. If childhood leukemia were to have a predominantly genetic cause, monozygotic twins would be expected to be concordant for leukemia more often than dizygotic twins because of their genetic similarity. If childhood leukemia were caused by an abnormal intrauterine environment, it would be expected that if one member of a dizygotic twin pair were affected, the other twin would be affected more often than a nontwin sibling because of the shared environment. Recently, in a study of leukemia in a pooled series from the United States, Canada, and England, only three concordant pairs (1.5%) were found among 197 pairs in which one or both twins had leukemia, with the concordance rate for monozygotic twins reported to be 3.9% (95% confidence interval [CI], 0.8 to 11.1).[80] Although the concordance rate in twins of like sex (probably monozygotic twins) is higher than the zero concordance rate reported for twins of unlike sex (dizygotic twins), the concordance rate in twins of like sex is quite variable.[80,81] These findings suggest that inherited genetic factors most likely play a relatively small part in the cause of childhood leukemia.

The occurrence of concordant leukemic pairs has been hypothesized to be due to parallel expansions of clones descended from a single, ancestral cell transformed in utero, with a malignant clone arising in one monozygotic twin and entering the circulation of the co-twin through anatomizing placental vessels. This mechanism would account for the early and similar age of onset of leukemia and the similar cytogenetic findings.[82,83] Support for this hypothesis is provided by the recent observation of shared clonal but nonconstitutional mixed lineage leukemia gene (*MLL)* rearrangements in the leukemic cells of three pairs of monozygotic twins concordant for infant acute leukemia.[84] The rearrangements were not observed in nonleukemic cells of the twins and were not present in the maternal or paternal blood of two of the three twins.

Leukemia and Cancer in the Families of Children with Leukemia

In studies of leukemias of all types combined, no excess of cancer was observed among siblings, parents, or offspring.[85-91] In studies focusing on acute leukemia, an excess of acute leukemia was observed among siblings, in whom the expected rates were extremely low.[92-94] Limitations of these studies include the inclusion of distant relatives, in whom verification of cancer becomes problematic, incomplete follow up, and, finally, the inclusion of families with a history of consanguinity.

Cancer in Offspring of Patients Treated for Childhood Leukemia

Few studies have reported the rate of occurrence of cancer in the offspring of patients treated for childhood leukemia. Only recently have enough patients survived that the number of their offspring permitted estimates of their risk of developing malignant neoplasms. After performing a review of the literature, Hawkins and associates[89] estimated that the proportion of heritable cases among survivors is unlikely to exceed 5%, assuming that the age of onset of all heritable cases is 15 years of age or younger and that the diseases had a penetrance of 70% or more. Chromosomal instability was examined in 20 apparently healthy children of survivors of childhood malignancy. Compared with control subjects, no increases in spontaneous or bleomycin-induced aberrations were found in these “index children.” The results suggest that the offspring of subjects who previously received chemotherapy, radiotherapy, or both for childhood malignancy probably have no increased risk of latent chromosomal instability.[95]

Other Conditions in Relatives of Patients with Leukemia

Savitz and Ananth[96] reported an excess of major birth defects among the siblings of patients with ALL (relative risk [RR], 3.2; 95% CI, 1.3 to 7.7; adjusted for age at diagnosis, sex, and year of diagnosis). Mann and colleagues[97] reported an excess of congenital defects among parents, uncles, aunts, and other distant relatives of patients with ALL compared with community control subjects. Buckley and associates[98] reported an excess of a number of conditions in siblings, parents, and grandparents of index patients with various types of ALL. These conditions included musculoskeletal disorders among relatives of patients with the common cell type; gastrointestinal, hematologic, and musculoskeletal disorders and allergies for those with the pre–B-cell type; an excess of gastrointestinal disorders for those with the T-cell type; and an excess of congenital heart and lung disease for those with the null cell type. The offspring of adult survivors of childhood ALL were not found to have an increased risk of occurrence of congenital anomalies compared with the offspring of sibling control subjects.[98] Similarly, Kenney and colleagues[99] reported no excess of congenital anomalies among the offspring of adult survivors of childhood cancer compared with the offspring of sibling control subjects.

Human Leukocyte Antigen–DR and Susceptibility to Childhood ALL

Both genetic and environmental factors could possibly play an interactive role in the development of childhood ALL. Because of the demonstration of the influence of major histocompatibility complex on mouse leukemia, a human leukocyte antigen (HLA) association has been considered as a possible genetic risk factor. Dorak and associates[100] demonstrated a moderate association with the most common allele in the HLA-DR53 group, HLA-DRB1*04, which was stronger in males. In addition, homozygosity for HLA-DRB4*01, encoding the HLA-DR53 specificity, was increased among patients. Confounding these associations was a male-specific increase in homozygosity for HLADRB4*01. The cross-reactivity between HLA-DR53 and H-2Ek, extensive mimicry of the immunodominant epitope of HLA-DR53 by several carcinogenic viruses, and the extra amount of deoxyribonucleic acid (DNA) in the vicinity of the *HLA-DRB4* gene provide arguments for the case that HLA-DRB4*01 may be one of the genetic risk factors for childhood ALL. Comparison of DQA1 and DQB1 alleles in 60 children with ALL and 78 newborn infants (control subjects) revealed that male but not female patients had a higher rate of occurrence of DQA1 *0101/*0104 and DQB1 *0501 than did appropriate control subjects.[101] The authors concluded that this finding represented a male-associated susceptibility haplotype in ALL, supporting an infectious cause. Additional investigations from the United Kingdom have suggested that cALL in children may be associated with HLA-DPB1 through a mechanism that involves the presentation of specific antigenic peptides, possibly derived from infectious agents, which leads to activation of helper T cells that mediate proliferative stress on preleukemic cells.[102]

Susceptibility to Childhood ALL: Genetic Polymorphisms

In the search for gene-environment interactions in the cause of childhood leukemia, investigations have focused on the genetic variability in xenobiotic metabolism, DNA repair pathways, and cell-cycle checkpoint functions that might interact with environmental factors to influence leukemia risk. Although much of the research in this area has been limited by small sample size, data suggest a potential role for polymorphisms in genes encoding cytochrome P450, glutathione S-transferase, reduced nicotinamide adenine dinucleotide phosphate quinone oxidoreductase, methylenetetrahydrofolate reductase (MTHFR), cycle-cycle inhibitors, and DNA-repair polymorphisms.[103-111]

In general, few reports have addressed the potential role of these polymorphic genes in childhood leukemia, and in many instances they provide contradictory findings. This situation is particularly true with regard to studies of GSTM1 and GSTT1 and CYP-P450 enzymes.[112,113] Low folate intake or alterations in folate metabolism as a result of polymorphisms in the enzyme MTHFR have been associated with neural tube defects and some cancers. Polymorphic variants of MTHFR lead to enhanced thymidine pools and better quality DNA synthesis that could afford some protection from the development of leukemias, particularly those with translocations. Wiemels and colleagues[103] and Smith and colleagues[111] reported an association of MTHFR polymorphisms in infant leukemias with *MLL* gene rearrangements and childhood leukemia with either *ETV6-RUNX1* fusions or hyperdiploid karyotypes. These studies provide evidence that molecularly defined subgroups of childhood leukemias may have different causes and also suggest a role for folate in the development of childhood leukemia. In a case-control study, MTHFR genotypes TT677/AA1298 and CC677/CCC1298 were associated with a reduced risk of childhood ALL.[114] Moreover, the findings of these studies suggested a gene-environment interaction based on timing of implementation of folic acid supplementation in the Canadian population. To date, no direct gene-environment associations have been established convincingly. When considering the potential importance of the prenatal origin of childhood leukemia, it becomes important to consider the genotypic profile of the mother with respect to metabolizing enzymes. Investigation of maternally mediated genetic effects through reduced nicotinamide adenine dinucleotide phosphate quinone oxidoreductase did not affect risk for childhood ALL.[115]

PRENATAL ORIGIN OF CHILDHOOD ALL

As mentioned earlier, molecular studies on several pairs of identical twins, aged between 2 months and 14 years at diagnosis, first provided strong evidence that concordant ALL arises in monozygotic twins after mutation and clonal expansion of one cell in one fetus in utero.[84,116,117,118,119] Because the disease in the twins is not clinically or biologically different from that in singletons, Gale and associates[119] hypothesized that some of the singletons are likely to have a prenatal initiation of their leukemia. They further hypothesized that an additional event or exposure postnatally results in the clinically overt leukemia at a variable time after birth. To test these hypotheses, they used the neonatal blood spots or Guthrie cards[119] to identify the presence of clonotypic or patient-specific leukemia fusion-gene sequences *(ETV6-RUNX1)*.[120] The association between the t(12;21) and the deletion of the nontranslocated allele of *TEL* is among the most frequent abnormalities observed in B-lineage ALLs.[121] Neonatal blood samples are routinely used to screen for inherited metabolic disorders. By reverse-transcriptase polymerase chain reaction screening of blood or bone marrow, the investigators identified *ETV6-RUNX1* fusion in 12 children and a pair of identical twins, aged 2 to 5 years, with newly diagnosed ALL. They identified *ETV6-RUNX1* fusion sequences in blood spots from the identical twins and in six of the nine studied ETV6-RUNX1–positive patients. Gale and colleagues concluded that childhood ALL is often initiated by a chromosome translocation event in utero. This important observation has been more extensively investigated and characterized.[122,123] Screening of neonatal cord/blood samples has revealed a putative leukemia clone with the *ETV6-RUNX1* fusion gene in 1% of newborn babies,[124] which represents a frequency 100 times greater than the prevalence of ALL defined by this fusion gene later in childhood. In children with cALL who have a *ETV6-RUNX1* fusion gene, deletion of the unrearranged or normal *TEL* allele is a common secondary occurrence. The causal events that lead to the initial *ETV6-RUNX1* fusion in utero and any postnatal secondary mutations are not known.[125] Some epidemiologic data provide support for the idea that an abnormal immunologic response under particular social conditions could account for certain critical postnatal events.[13,126] Further epidemiologic studies need to focus on in utero exposures that could result in the initial *ETV6-RUNX1* fusion and postnatal exposures or events that could explain the secondary mutations.

INFECTION

Considerable interest and research has focused on the potential role of infection in the cause of childhood ALL through a mechanism of stimulation of an inappropriate immune response or via a direct transformation.[127] This avenue of research, proposed and spearheaded by British researchers, reflects two different but conceptually related hypothesized mechanisms.

The Kinlen Hypothesis: Residence in Areas with High Population Mixing

In 1988 Kinlen[128] hypothesized that the high incidence of leukemia in children in the vicinity of the Sellafield and Dounreay nuclear reprocessing plants in England could be due to a rare response to some unidentified mild and subclinical infection, the transmission of which is facilitated by contacts between large numbers of people. An influx of people of diverse origin into a previously isolated area would particularly facilitate transmission. Thus a high incidence of leukemia in childhood would be expected in isolated areas into which a significant influx of people had occurred. The hypothesis was first tested in an area in Scotland. Glenrothes New Town was identified a priori as an area where, after a period of relative isolation, a sudden burst of in-migration occurred in 1964 because of the opening of the Forth Road bridge.[128] A significant number of persons younger than 25 years who died of leukemia were identified during the period from 1951 to 1967. The incidence of leukemia was not excessive in the period from 1968 to 1985, when the community became much less isolated. The hypothesis has been tested in a number of other situations in England, France, and other parts of Europe and Hong Kong.* A 3.6-fold increase in childhood leukemia was observed in the wartime cohort compared with national Scottish rates in Orkney and Shetland (England's northernmost islands) during World War II, when the local people were outnumbered by servicemen stationed there. The rates normalized to the national rates in the postwar period.[141] A recent analysis of the U.S. Surveillance Epidemiology and End Results data also provided confirmatory evidence for the population mixing hypothesis, with findings that changes in rural county population sizes from 1980 to 1989 were associated with increased incidence rates for childhood ALL.[142]

Infections during the Index Pregnancy

An alternative model for the cause of childhood ALL places the critical infectious event during pregnancy rather than early childhood. In this model, the etiologic agent causing the primary infection in the mother is transmitted to the fetus, and as a consequence of this in utero infection, the child is at increased risk for the development of ALL before the age of 5 years. The characteristics that the causative infectious agent should possess include: (1) the ability to induce genomic instability, (2) specific effects on B lymphocytes and not on T lymphocytes, (3) higher rates of infection in regions with lower socioeconomic status, (4) limited general oncogenic potential, (5) minimal symptoms associated with the primary infection, and (6) the ability to cross the placenta and infect the fetus but not result in severe fetal abnormalities. A virus that meets several of these criteria is the JC virus, a member of the polyomavirus family.[143]

The possibility that maternal infection during pregnancy could potentially be leukemogenic is supported by the observation that leukemia in cats is caused by a feline virus transmitted from the mother to the fetus.[144] Three cohort studies of maternal infection during pregnancy and subsequent childhood cancer revealed an excess of cancer in these children compared with the age- and sex-matched general population.[145-147] In case-control studies, no association between maternal infection with influenza or varicella and subsequent childhood cancer was seen.[98,148-153] With regard to maternal infection in general, a twofold excess of childhood cancer has been reported. However, the studies are small or the reported prevalence of exposure is low and may be attributed to recall bias. Neonatal blood spots have been used to identify evidence of selected in utero viral infections.[154,155] Investigation of cytomegalovirus and human parvovirus B19 infection failed to identify DNA in the small groups of childhood ALL cases compared with healthy control subjects. First-trimester serum samples from mothers of children diagnosed with ALL derived from large maternal cohorts in Finland and Iceland have been tested for antibodies to *Chlamydia trachomatis*, *Helicobacter pylori,* and *Mycoplasma pneumonae*.[156] Comparison of ALL cases to control subjects identified an increased risk associated with *M. pneumoniae* immunoglobulin M and, in Iceland, *H. pylori* immunoglobulin G. Within the same maternal cohort, evidence was found for activation of maternal Epstein-Barr virus infection in both childhood ALL and non-AML cases.[157]

Smith and colleagues[158] sought to assess the relationship of childhood ALL with hygiene conditions, an aspect of socioeconomic development affecting rates of exposure to infectious agents. The data suggested that improved public hygiene conditions measured by decreased prevalence of hepatitis A virus infection (an agent with a fecal-oral route of transmission) were associated with high childhood ALL incidence rates. The model presented in this study supports the plausibility of the hypothesis that decreased childhood exposure to a leukemia-inducing agent associated with hygiene conditions leads to higher rates of ALL in children by increasing the incidence of in utero transmission caused by primary infection during pregnancy (or by increasing the number of persons infected in early infancy because of a lack of protective antibodies).

Antibiotic Use and Immunizations during the Index Pregnancy

No association between antibiotic use during pregnancy and leukemia has been identified.[148,150,152,159-161] No consistent association has been reported between vaccination during pregnancy and leukemia. Salonen and Saxen[162]

---

*References 6, 12, 25, 49, 129-134, **135**, 136-140.

found a positive association between leukemia and maternal polio vaccination during pregnancy. Similarly, Gilman and associates[160] reported a positive association between total childhood deaths and vaccination during pregnancy that was largely accounted for by neoplasms of the reticuloendothelial system. However, results of a population-based study in the Netherlands showed no association between vaccination during pregnancy and ALL.[150]

Association of Childhood Leukemia with Factors Related to the Immune System

It has been proposed that some instances of pediatric ALL arise as a rare response to a common childhood infection and that the leukemia-inducing potential of the agent is related to the timing of infection, with a greater leukemogenic effect for later infections compared with those occurring during infancy.[163] In this context, factors related to the child's immune system are of special interest. Several investigators have sought to identify factors such as birth order and breastfeeding that can potentially be used as markers of infections or confer protection against infection before the diagnosis of leukemia.[164]

Breastfeeding

Breastfeeding is well known to have a protective effect against infection in infants.[165] Data regarding the association between breastfeeding and subsequent childhood leukemia are important because of the proposed hypothesis about the etiologic role of infections, taking into consideration the fact that breastfeeding protects against infections. This association was examined in several studies with mixed results. Whereas some researchers failed to show any association between breastfeeding and childhood leukemia,[152,166-172] other researchers do show that a protective effect is offered by breastfeeding.[173] A report of a large North American case-control study revealed that breastfeeding was associated with a reduced risk of childhood acute leukemia.[173] The inverse association was stronger with a longer duration of breastfeeding for patients with ALL and AML. A recent meta-analysis suggested that breastfeeding of any duration was associated with a 9% lower risk of ALL, but little evidence was found of an association for risk of childhood AML.[174]

Immunizations

Previous studies suggested that vaccinations during infancy may reduce the risk of subsequent childhood leukemia. No consistent association between leukemia and immunization has been identified, although two recent studies suggested that early immunization against *Haemophilus influenzae* type b may reduce the incidence of childhood leukemia.[175,176] Auvinen and associates[176] compared the vaccination histories of 439 children in whom ALL was diagnosed and 439 community control subjects matched to patients with regard to age, race, and telephone exchange. No association was demonstrated between most infant vaccinations such as oral poliovirus, diphtheria-pertussis-tetanus, and measles-mumps-rubella. However, infants receiving the conjugate *H. influenzae* type b vaccine had a reduced risk for subsequent childhood ALL. Confirmatory studies are needed.

Sibship Size

Sibship size might be an indirect indicator of exposure to common childhood infections. However, although no consistent association between ALL and sibship size has been identified,[177] authors of a study from Canada reported that when all variables defining family structure are included in a model, having older siblings at the time of diagnosis was a risk factor among children in whom ALL was diagnosed before 4 years of age, whereas having older siblings in the first year of life was a protective factor among children in whom ALL was diagnosed at 4 years or later.[171] More recently, analysis of the Swedish Family-Cancer Database demonstrated that having three or more older siblings is associated with a significantly reduced risk of childhood AML and ALL.[178]

Early Child Care and Preschool Experiences

Day care of the index child and of siblings has been used as a proxy measure of exposure to infections. The findings of case-control studies have been inconsistent regarding association between attendance at day care centers and risk of leukemia.[177,179-185] A recent study conducted by the United Kingdom Childhood Cancer Study (UKCCS) investigators was specifically designed to test the early infection hypothesis, including the role of day care. These investigators found that increasing levels of social activity were associated with reductions in the risk of ALL in a dose-response manner.[185]

Infection and Related Exposures during the Lifetime of the Index Child

Studies of an association between childhood cancer and postnatal infection of the index child are problematic because of the difficulty in assessing whether the episodes of infectious disease were a possible cause of the childhood cancer or represented a prediagnostic sign of the disease. Some investigators have attempted to overcome this concern by restricting attention to infection during the first year or first 6 months of life or by considering infections reported only during a specified period before diagnosis in patients and during a reference time in control subjects. Specifically, investigators explored the role of parvovirus B19 with its hematotropic effects and the potential to precipitate varying forms of cytopenia in patients before or after the diagnosis of ALL,[186] but they failed to find an association between parvovirus B19 and childhood ALL. Other epidemiologic studies have provided inconsistent findings for an association between leukemia and recorded or reported infections in early life.[98,149,153,167,186-191] In the UKCCS investigation, which utilized general practitioner records for visits during the first year of life, it was found that children with ALL who were diagnosed between the ages of 2 to 5 years had significantly more clinically diagnosed infectious episodes in infancy.[191] Another case-control study from the UKCCS group explored the relationship between childhood leukemia, infant infection, and three markers of infection exposure: birth order, infant day care attendance, and area-based deprivation. The study findings indicated that immune dysregulation among children who are diagnosed with ALL is detectable from an early age.[192] Moreover, recent epidemiologic data indicate that the risk of cALL is increased by higher socioeconomic status, isolation, and other community characteristics suggestive of abnormal patterns of infection during infancy,[13] and population-based incidence patterns have identified small peaks in the incidence of childhood ALL that coincide with years immediately following influenza epidemics.[42]

Chloramphenicol

Chloramphenicol can cause bone marrow suppression and could potentially play an etiologic role in childhood leukemia. Shu and colleagues[193] reported a positive association with the use of chloramphenicol from a study conducted in Shanghai. The risk of leukemia associated with chloramphenicol use increased with an increasing total number of reported days of use. The association was stronger for AML than for ALL. A major limitation of the study was the long interval between diagnosis (1974 to 1986) and interview (1985 to 1986) for the patients, whereas the control subjects were recruited in the 2-year period of 1985 to 1986.

Index Child's Contact with Animals

Although considerable interest has been generated in a possible role of feline leukemia virus because of similarities between human and feline ALL in clinical findings, laboratory data, and response to treatment,[194] evidence is lacking for a biologic association.[195]

Bovine leukemia virus has also been studied for a possible role in the cause of human leukemia. A case-control study of 131 children with leukemia and 136 regional population control subjects was conducted to investigate this association. However, none of the DNA samples from patients or control subjects hybridized with a bovine leukemia virus DNA probe, providing strong evidence that genomic integration of bovine leukemia virus is not a factor in childhood ALL.[196]

Buckley and associates[98] reported a positive association with exposure of the mother, father, and index child to farm animals, compared with control subjects who had other types of cancer or community control subjects. However, no overall association with cat ownership was identified. A recent large case-control study failed to show any association between pet ownership and childhood acute leukemia.[197]

Leukemia and Bacillus Calmette-Guérin Vaccination

Laboratory evidence that tubercle bacilli of the Calmette-Guérin strain (BCG) can prevent or suppress challenge from leukemia or tumor grafts in laboratory animals[199] led investigators to explore whether BCG vaccination might reduce the incidence of cancer in humans and of leukemia in particular. However, no consistent association between BCG vaccination and the subsequent risk of leukemia was found.[198-201]

Seasonal Variations in the Onset of Childhood Leukemia

Seasonal variations in onset of disease could provide supportive evidence of an infectious cause. Westerbeek and colleagues[202] demonstrated significant seasonal variation in the date of the first symptom of childhood ALL, with peaks occurring in November. However, a larger study of 15,835 patients with childhood leukemia failed to reveal any evidence of seasonality in either month of birth or month of diagnosis overall or in any subgroups by age, sex, histologic analysis, or immunophenotype.[203] However, this study did find a statistically significant February peak in month of birth for patients born before 1960 and an August peak in month of diagnosis for patients in whom leukemia was diagnosed before 1962. Although these findings may be due to chance, they are also consistent with changes over time in the seasonality of exposure or immunologic response to a relevant infection. Changes in the seasonal variation in the fatality rate of a preleukemic illness, such as pneumonia, could be another explanation. Ross and associates[204] examined data from the Children's Cancer Group and the Pediatric Oncology Group for seasonal variation patterns. A statistically significant seasonal variation for ALL was found, with a peak in the summer. Biologic mechanisms underlying these seasonal patterns are probably multifactorial and need to be investigated.

ENVIRONMENTAL EXPOSURES

Although a large body of literature describes the associations between a variety of environmental exposures and childhood leukemia, insufficient evidence exists for a causal relationship in most exposure studies, with the exception of those for ionizing radiation. Retrospective studies are limited because of the reliance placed upon parental self-report of the exposure in the context of a case-control study design, which can be hampered by recall bias. In addition, the nonspecific nature of the exposure being assessed makes it difficult to explore causal mechanisms involved with the associations. Moreover, a majority of the exposure assessment has focused on paternal exposures, with little emphasis placed on maternal exposures. To more clearly evaluate the importance of these exposures in future investigations, improvement is needed in the following areas: (1) importance given to maternal exposures; (2) sophisticated exposure techniques used; (3) attention paid to the mechanism, timing, and route of exposure; and (4) the provision of evidence that the exposure is actually transferred to the child's environment.

Radiation Exposure

In utero exposure to radiation has been reported to be associated with a small yet statistically significant increased risk of development of childhood leukemia in numerous case-control studies.[†] Reported estimated risks generally ranged from 1.1 to 2.0, with most of the risk ratios being equal to or lower than 1.6. It is reasonable to expect that in utero levels of exposure to radiation would have declined substantially over time given the knowledge of health-related risks associated with radiation exposure and the reduced level of radiation required for diagnostic procedures. Studies from Sweden, England,

---

[†] References 166, 205-208, **209**, 210-213.

and the United States have demonstrated higher risk estimates among children born in earlier eras (e.g., the 1930s to 1950s) compared with more recent periods.[213-216] Nonetheless, the potential role of in utero exposure to radiation in childhood leukemia has remained controversial. Much of the debate has focused on the lack of an observed association among offspring of mothers who were exposed while pregnant at the time of the Hiroshima and Nagasaki atomic bombs[217,218] coupled with concerns regarding the lack of good exposure assessment and the potential for recall bias in case-control studies of the topic. Results from a large case-control study in North America did not identify an overall increased risk associated with in utero pelvimetric diagnostic x-rays or associations within subgroups defined by immunophenotype.[219] It is likely that the reduced rate and dose of exposure in North America has resulted in an inability to detect the small risk that may exist.

In contrast to the in utero data, postnatal exposure to radiation has not been consistently associated with the risk of childhood leukemia.[166,206,212] Regardless, even if leukemia risk is increased, the potential number of instances of leukemia that currently might be attributed to in utero or postnatal exposure to radiation would probably be very small when one considers the modest magnitude of risk and the limited level of exposure. Results of a case-controlled study of 302 cases of infant leukemia suggested that paternal low-level radiation exposure before conception is associated with an increased risk of infant leukemia, although the nature of this association needs to be further evaluated.[220]

A number of investigations of environmental exposures of children to sources of radiation from nuclear detonations and power plants were conducted to determine the potential impact on leukemia risk. In studies of children who survived the atomic bombs of Hiroshima and Nagasaki, an increased occurrence of leukemia 5 to 15 years later was seen.[221] Leukemia risk was positively correlated with the dose of radiation among the atomic bomb survivors. Reports relating to follow-up of nuclear accidents at Three Mile Island and early reports from Chernobyl did not provide strong evidence of an increased risk of childhood leukemia. Analyses that included residents in the area surrounding the Three Mile Island facility did not reveal an increase in the ratio of observed to expected incidence of leukemia.[222] Similarly, investigation of specific regions of the former Soviet Union did not reveal increased rates of childhood leukemia within the first 5 years after the Chernobyl accident.[223] Because of the widespread fallout from Chernobyl, a series of investigations were undertaken in affected countries, including Sweden,[224] Finland,[225] England,[226] Scotland,[227] Germany,[228] and Greece.[229] With the exception of higher rates in Scotland and an observed excess of infant leukemia (i.e., in children younger than 1 year) in Greece,[230] results were generally negative for an observed increase after the accident. The most recent investigation of the acute and long-term risks for childhood leukemia resulting from radiation exposure (a median estimated dose of <10 mGy) after the Chernobyl power station accident identified a significant increase in leukemia risk with increasing radiation dose to the bone marrow.[231] However, the potential overestimate of childhood leukemia risk within one region raised serious concerns about conclusions that could be drawn with regard to the level of risk resulting from the Chernobyl accident.

During the 1950s, testing of nuclear weapons took place in Nevada, with nuclear fallout affecting regions of Nevada and Utah. Studies were carried out in Utah to determine the potential impact on childhood leukemia, using geographic region–specific radiation dose estimates to the bone marrow. No significant trend between estimated dose and risk of leukemia mortality was found.[232] However, the risk of death from leukemia was found to be higher in those exposed at the highest dose level (6 to 30 mGy) compared with those in the lowest dose group (0 to 2.9 mGy).

During the past several decades, the potential impact of nuclear facilities, either nuclear energy plants or nuclear reprocessing plants, has generated considerable interest with regard to cancer risk among surrounding residents. Studies addressing childhood leukemia have been conducted in England,[233,234] France,[235,236] the United States,[237,238] Germany,[239] and Canada.[240] In aggregate, these investigations have not provided strong evidence of an increased occurrence of childhood leukemia, although several have reported increases in incidence and mortality.

Although the biologic plausibility of indoor radon exposure and the cause of childhood leukemia are speculative[241] and debatable,[242] studies have been conducted to address the topic. Although ecologic investigations have provided some evidence for a correlation,[241-243] case-control studies incorporating measurement of indoor radon levels have not found higher levels within homes of children with ALL[244] or AML.[245]

Parental Occupational Exposures

Occupational exposure of parents and its association with childhood leukemia have been the subject of several investigations.[246-249] Occupations and exposures of fathers were investigated more often than were those of the mother. Detailed assessment with use of a job exposure matrix to classify occupational exposures identified an increased risk for childhood AML in association with maternal exposure to 1,1,1-tricholorethane, toluene, mineral spirits, alkanes, and mononuclear aromatic hydrocarbons, although dose-response associations were not present.[249] Exposure in the home was not associated with increased risk. Investigation within the UKCCS identified small but statistically significant increased risks among children with ALL whose fathers reported their occupation to involve motor vehicle driving and were exposed to exhaust fumes and/or inhaled particulate hydrocarbons.[248] The studies have several limitations related to the quality of exposure assessment, small numbers of exposed children, multiple comparisons, and possible bias toward the reporting of positive results. Although some evidence exists for an association between childhood leukemia and paternal exposure to solvents, paint, and employment in motor vehicle–related occupations, clearly established associations between parental occupation and childhood leukemia are lacking.

Exposure to Chemicals and Dust

Pesticides

The association between pesticides—including insecticides, fungicides, and herbicides—and childhood leukemia has generated considerable interest, primarily because of the observed higher incidence of leukemia in rural areas and because of the biologic activity of these chemicals. Leiss and Savitz[250] reported a positive association between the use of pest strips and childhood leukemia. The insecticide used in pest strips was dichlorvos, an organophosphate that has been associated with adult-onset leukemia in men.[251] Authors of another study reported an association between the use of pesticides in gardens and farms and childhood leukemia,[252] but no association of leukemia with reported home pest extermination was found in this study. A positive association between maternal exposure during pregnancy and lactation and paternal exposure to household pesticides and garden pesticides or herbicides during the time the mother was pregnant was reported by Lowengart and associates.[253] A recent study provides further evidence for an association between an increased risk of leukemia and rural residence and use of household pesticides.[254] Authors of several other studies report an association between pesticide exposure and childhood leukemia.[255,256]

In a multicenter study of 404 patients who had ALL and individually matched community control subjects, Buckley and associates[98] reported a positive association between ALL and both paternal exposure (RR, 2.8; $P < .001$) and exposure of the index child (RR, 5.0; $P < .001$) to insecticides. The strongest associations for both paternal exposure and exposure of the index child were apparent for T-cell and common cell ALL.

In another case-control study consisting of 204 patients with AML and matched community control subjects, Buckley and associates[257] reported a positive association with maternal occupational exposure to pesticides before, during, and after pregnancy and paternal occupational exposure during the same period. In addition, an independent association of maternal exposure to household fly sprays, pesticides, and garden and agricultural sprays and treatment of the house by insect exterminators in the month before the last menstrual cycle and during the index pregnancy was found, along with direct exposure of the index child to household and garden insecticides. These associations were independent of parental occupational exposure.

Thus, although a large body of literature exists regarding the association between pesticide exposure and childhood leukemia,[255,256] the studies are limited by the nonspecific nature of the exposure, the reliance of these studies on parental self-report, and the lack of sufficient evidence for a causal relationship. Moreover, use of pesticides may be an indicator of rural isolation, and thus there is a possible confounding effect because of the patterns of exposure to infection that may be associated with population mixing.

Agent Orange. Wen and colleagues[258] reported a small increase in the risk of the diagnosis of AML before the age 2 years among offspring of veterans who had served in Cambodia or Vietnam.[258] The etiologic importance of these observations remains to be determined. Exposure to Agent Orange was evaluated in this study, but no association was identified. Other studies also concluded that exposure to the herbicides in Agent Orange was not associated with an increased risk of childhood leukemia among the children born to veterans who reported the exposure.[259]

Hydrocarbons and Solvents

Parental exposure to hydrocarbons at work has been investigated as a potential risk factor for childhood leukemia, with no consistent association between paternal or maternal occupational exposure to hydrocarbons and leukemia (all types and specifically ALL).[260-264] Similarly, no association between paternal exposure to benzene and leukemia has been found.[253,257,262-265] Maternal occupational exposure has been less well studied, but in two of the three studies, a positive association with maternal occupational exposure to hydrocarbons was found that is compatible with the observation that benzene is associated with AML in adults.[162,193,257] Two studies indicated that maternal exposures to hydrocarbons during the preconception period, during pregnancy, and during the postnatal period were related to an increased risk of ALL.[266] A positive association between ALL and paternal exposure to hydrocarbons during the preconception period was also found.

No clear association with residential proximity to industrial sources of hydrocarbons has been observed,[267,268] although authors of one study reported an increased risk of childhood leukemia, and AML in particular, associated with living near petrol stations and/or repair garages.[264] An increased risk of childhood leukemia associated with paternal occupational exposure to chlorinated solvents was reported by several investigators.[253,257,263] The risk has been assessed for exposure during the periods of 1 year before pregnancy, during pregnancy, and after delivery.[257] Several investigators reported a positive association with postnatal exposure of the index child to solvents.[98,153] No consistent association with maternal exposure to solvents is apparent.[269] A recent study revealed a significant association between substantial participation by household members in some common household activities involving organic solvents and childhood leukemia,[270] but further substantiation of these findings is necessary.

Metal Dusts and Fumes

A positive association between the total reported duration of paternal occupational exposure to lead and AML has been reported by Buckley and associates.[257] In the same study, these investigators reported an association between maternal occupational exposure to "metal dusts and fumes." Similar findings were reported by Shu and colleagues[193]; in their study in Shanghai, maternal occupational exposure to lead was associated with an increased risk of acute leukemia. A positive association between maternal exposure to molten metal and ALL (null cell and T cell) and a positive association between paternal exposure to metals and T-cell ALL have been reported.[98] However, ecologic studies have failed to show an association between leukemia and proximity to industrial facilities with an increased exposure to metal or metal fumes.[271,272]

Wood Dust

An association between maternal occupational exposure to wood dust before conception of the index child and childhood leukemia and non-Hodgkin lymphoma has been reported. A few women were exposed during or after pregnancy.[263] Significantly elevated RRs have been reported for paternal occupational exposure to wood dust before conception, during the periconceptional and gestational periods, and postnatally.[246] The association of exposure to wood dust and leukemia was studied by Buckley and associates.[98,257] They found that the risk was elevated compared with that for other cancers and also compared with that for community control subjects.

Traffic

Occupational exposure to elevated concentrations of benzene is a known cause of leukemia in adults. Concentrations of benzene from motor vehicle exhaust fumes could be elevated along highly trafficked streets. The hypothesis that exposure to traffic-related air pollution increases the risk of development of childhood cancer was examined by several investigators.[273-275] Results indicate that an association might exist between residence on a busy street and childhood leukemia. However, these results need to be viewed with caution, because most of the results are based on ecologic studies, with an imperfect assessment of individual exposure.

Electromagnetic and Radiofrequency Field Exposure

An initial report in 1979 suggested an association between childhood leukemia and residential proximity to sources of electric and magnetic fields, as assessed by wiring configurations.[276] Subsequently, a large number of investigations have been conducted to further evaluate the hypothesis that exposure to extremely low-level electric and magnetic fields may influence the risk of childhood leukemia and other pediatric malignancies.[‡] These studies, although they provide some consistent findings, are difficult to interpret given the inconsistencies observed in associations between inferred exposure (i.e., wire configuration) compared with measured fields.

Moreover, many of these studies are limited by small sample size and the inability to adequately consider potential confounding factors within the analysis. Three of the more recently reported investigations from the United States,[287] Canada,[288] England,[289,290] and Japan[291] provide rather convincing evidence that electric and magnetic field exposure is not associated with a significantly increased risk of childhood ALL. Nonetheless, results of meta-analyses[292,293] have been interpreted to suggest that risk may be increased at the highest exposure levels (i.e., >0.4 μT). However, it is important to note that even if an increased risk does exist at this highest exposure level, the proportion of the population exposed is extremely small and thus the attributable risk would be negligible. Beyond investigation of risk for leukemia, reports have been made of possible associations between electric and magnetic field exposure and prognosis.[294,295]

Although not as extensively studied as electric and magnetic fields, radiofrequency exposure has been suggested as a possible cancer-related risk factor.[296] A recent report investigating radiofrequency exposure in 1928 patients with childhood leukemia observed a twofold risk associated with living within 2 km of an amplitude modulation radio transmitter, which was statistically significant in a dose-dependent fashion for childhood ALL.[297]

LIFESTYLE

Maternal Diet and Vitamin Supplement Use during Pregnancy

Diet and use of vitamin supplements have been shown to be associated with the risk of several cancers among adults. In pediatric malignancies, research has focused primarily on use of vitamin supplements during pregnancy, with little attention given to diet.[159,298] Investigation of maternal diet during pregnancy of children with ALL between the ages of 1 to 5 years found that ALL risk was statistically significantly lower with increased consumption of fruits, vegetables, and fish/seafood, with a significantly higher risk related to increased maternal intake of sugar/syrups and meat products, but these findings will require confirmation in other populations.[299]

Among the available studies of childhood leukemia and maternal consumption of vitamin supplements during pregnancy, no association was found,[159,162,298] with the exception of one study reporting a decrease in risk of ALL among mothers who took iron supplements during the index pregnancy.[300]

Nearly 80% of infants with leukemia have a specific genetic abnormality in their leukemic blast cells involving the *MLL* gene on chromosome band 11q23.[301] Abnormalities involving 11q23 have also been reported in persons with secondary AML after exposure to topoisomerase inhibitors. Therefore Ross and colleagues[301] hypothesized that infant leukemias involving 11q23 may result from exposure to naturally occurring topoisomerase inhibitors. These agents include caffeine and a variety of fruit and vegetables. A subset of mothers of infants with leukemia diagnosed at 1 year of age or less and control children selected by random digit dialing included in three multicenter case-control studies of childhood leukemia in the United States[257,298] was reapproached to obtain additional information on maternal diet during the index pregnancy.[302] On the basis of data from a food-frequency questionnaire assessing consumption of 26 food items during the index pregnancy, no association was found between total estimated dietary intake of topoisomerase II inhibitors and leukemia of all types combined or ALL. However, a statistically significant positive association for AML was noted with increasing consumption of dietary topoisomerase II inhibitors. A study conducted in 2000 identified bioflavonoids, which are natural substances in food and in dietary supplements that cause site-specific DNA cleavage in the *MLL* breakpoint cluster region in vivo.[303] These results suggest that maternal ingestion of bioflavonoids may induce MLL breaks and potentially induce translocations in utero, leading to infant leukemia. In utero exposures and their association with infant acute leukemia were assessed by Alexander and associates.[304] Use of cigarettes and alcohol, the ingestion of certain herbal medicines and drugs classified as "DNA damaging," and exposure to pesticides were associated with an increased risk of leukemias associated with alterations in *MLL*.

Postnatal Diet of the Index Child and Use of Vitamin Supplements

The role of diet of the index child in the development of childhood leukemia has not been the subject of intensive investigation. Results of investigations exploring the association between the intake of certain food items thought to be precursors or inhibitors of N-nitroso compounds have been controversial. Some investigators report a positive association with hot dogs,[253] whereas others have failed to show any association with consumption of hot dogs or other cured meats.[298] No associations have been reported with postnatal use of vitamins by the index child[98] or consumption of fish, dried milk, fruit juice, or canned foods.[207]

Tobacco Smoking by Parents

Parental smoking and its association with childhood leukemia has been the focus of several investigations. However, issues such as publication bias (with a greater likelihood of positive associations being published) limit the quality of the data. In summary, the literature shows no consistent association between childhood leukemia and parental exposure to tobacco.

Furthermore, no consistent association between maternal smoking during pregnancy and leukemia[305-308] or between paternal smoking and all types of leukemia combined or AML has been found. In most studies, the period of exposure considered has been up to the birth of the index child. Although a positive association between paternal smoking and ALL has been reported by several investigators,[309-312] other investigators have failed to show any association.[305-308,313,314] The largest investigation of maternal smoking and risk of childhood leukemia, which was conducted in Sweden, included more than 1.4 million children born between 1983 and 1997.[315] In this study it was found that maternal smoking was associated with a lower risk of ALL but a higher risk of AML, particularly among heavy smokers. Sandler and associates[316] evaluated the cancer risk from cumulative household exposure to cigarette smoke in a case-control study. Cancer risk was greater for persons who were exposed during both childhood and adulthood than for persons who were exposed during only one period. Some evidence indicates that the effect of parental smoking could be modified to some extent by variant alleles in the *CYP1A1* gene.[306]

An earlier study reported an association between AML (type M4 or M5) and reported use of mind-altering drugs (primarily marijuana) by the mother in the year before or during the index pregnancy.[159] However, a subsequent investigation by the same investigators that was designed to test the hypothesis of maternal marijuana exposure failed to reproduce the association.[317] Thus, overall, maternal smoking during pregnancy or the exposure of infants to cigarette smoke shortly after birth is unlikely to contribute substantially to the risk of childhood leukemia. Moreover, it seems unlikely that passive smoke inhalation during childhood strongly affects the risk of development of childhood leukemia. However, the demonstration of genotoxic effects on the fetus of exposure to metabolites of tobacco smoke should lead to strong recommendations aimed at fully protecting fetuses, newborns, and infants from tobacco smoke.

Alcohol

The majority of studies pertain solely to alcohol consumption by the mother and only to consumption during the pregnancy leading to the birth of the index child. No consistent associations have been found between maternal alcohol consumption before or during the index pregnancy and leukemia of all types combined or ALL.[149,161,193,310] A recent report indicates that maternal alcohol consumption before (adds ratio [OR], 1.37; 95% CI, 0.99-1.9) or during pregnancy (OR, 1.39; 95% CI, 1.01-1.93) may contribute to an increased risk of childhood leukemia.[318] However, some evidence from a number of studies shows an association between maternal alcohol consumption and AML, primarily among persons in whom leukemia is diagnosed early in life. Severson and colleagues[305] reported an increased risk of AML among children in whom leukemia was diagnosed at or before 2 years of age and whose mothers reported consuming alcohol during their pregnancies; the association was particularly pronounced among patients with monocytic and myelomonocytic leukemia. However, the authors advised cautious interpretation of the data because of the small number of subjects included in the subgroup analysis. A positive association between alcohol consumption and AML has also been reported by others.[161,310] The risk appears to be increased for alcohol consumption during each of the three trimesters of pregnancy and for each type of beverage. A dose-response relationship is also suggested.[305,310] No association between paternal alcohol consumption and childhood leukemia has been found.[193,305,310]

MATERNAL REPRODUCTIVE HISTORY

Maternal Age and Birth Order

Accumulation of chromosomal aberrations and mutations during the maturation of germ cells are mechanisms hypothesized for the association between increasing maternal age and cancer in offspring. Most studies have failed to show an association between leukemia and maternal age.[193,319-322] However, a report from 1999 using the Swedish Family-Cancer Database revealed a maternal age effect for childhood leukemia (of about 50% greater in persons older than 35 years).[323]

Most studies based on index cases do not show a positive association with first birth. However, one of the largest of these studies revealed a decreasing trend with increasing birth order for children in whom ALL was diagnosed between the ages of 0 and 4 years.[322] This study also showed a positive association between AML and birth order, adjusted for age, sex, calendar period, and maternal age at the birth of the child. This association was also reported from a combined analysis of data for children who had AML that was diagnosed before 1 year of age in the United States.[319]

Prior Fetal Loss

The association between childhood leukemia and prior fetal loss has been examined by many investigators, with the reported RRs ranging from 0.3 to 1.8.[153,319,320] Data from a Children's Cancer Group case-control study were analyzed to test the hypothesis that this association depended on the number of previous fetal losses and age at leukemia diagnosis. Overall, a modestly increased risk of leukemia was found to be associated with a history of fetal loss. Stratification by age at diagnosis of leukemia showed that this association was significant only for patients in whom ALL and AML was diagnosed before 4 years of age and was most significant in patients in whom leukemia was diagnosed before 2 years of age.[324] Ross and associates[319] also reported a positive association between infantile AML and prior fetal loss. These reports suggested that childhood acute leukemia occurring at younger ages may be associated with an underlying genetic abnormality or chronic environmental exposure, which can be either lethal to the developing fetus or mutagenic and result in the development of acute leukemia.[319]

Oral Contraceptives

McKinney and associates[152] reported no association between leukemia and an interval of less than 3 months between when a woman stopped taking oral contraceptives and conception. Van Steensel-Moll and colleagues[150] reported no association between childhood leukemia and any use of oral contraceptives.

Maternal Illness and Use of Medications during the Index Pregnancy

Ever since the use of diethylstilbestrol to treat women during pregnancy was causally linked with clear-cell adenocarcinoma of the vagina and cervix, several investigators have explored a possible association between use of medications during pregnancy and childhood cancer.

Van Steensel-Moll and colleagues[150] reported a significant positive association with "threatened miscarriage" and "drugs to maintain pregnancy." Another study reported a positive association with hormonal treatment for infertility in the preconceptual period and reported infertility investigations.[148] However, in 1991 Kobayashi and associates[325] from Japan showed that no instance of maternal ovulation induction was recorded for the mothers of 2301 children with leukemia. The Northern California Childhood Leukemia Study investigators observed a significantly increased risk of ALL among mothers reporting influenza/pneumonia during the index pregnancy.[300] Lastly, in the Children's Oncology Group study of 1840 childhood ALL cases, it was reported that significant associations existed with parental use of amphetamines or diet pills and mind-altering drugs before and during the index pregnancy.[326]

Ultrasound Examinations

No association has been found between routine ultrasound exposure in pregnancy and childhood leukemia.[219,327-329]

Anesthesia during Labor

No consistent association has been found between childhood leukemia and cesarean section, which is an indication for anesthesia during labor.[148,190,321] McKinney and associates[152] found a positive association between leukemia and use of narcotic and opioid analgesics, mainly dextropropoxyphene hydrochloride, and between leukemia and the use of barbiturates in labor, but other investigators failed to show any association.[148]

MEDICAL HISTORY OF THE INDEX CHILD

Wen and colleagues[330] investigated the association between childhood ALL and allergic disorders (e.g., asthma, hay fever, food or drug allergies, eczema, and hives) using a case-control study design. The results of this study were in agreement with those of most previous studies of adult cancer, suggesting that allergic disorders may be associated with reduced risk of childhood ALL.

Congenital Anomalies

The presence of cancer and congenital anomalies in the same child may sometimes be explained by an underlying genetic abnormality. A study of these associations might provide clues to the identification of genes that are important to the cause of childhood leukemia. The increased risk of leukemia associated with congenital anomalies appears to be accounted for largely by Down syndrome.[331] Children with Down syndrome have a thirtyfold increased risk of developing childhood leukemia, with the proportion of leukemia attributable to Down syndrome by age 14 years estimated to be 2.7%.[332] To evaluate the risk of leukemia associated with congenital anomalies, a series of matched case-control studies was carried out by the Children's Cancer Group.[333] A total of 2117 children in whom ALL was diagnosed and 605 children in whom AML was diagnosed were compared with matched regional population control subjects. Data on congenital anomalies in the index child were collected by telephone interview with the biologic mother. More congenital anomalies were reported in index case patients who had ALL than in control subjects and included statistically significant increases in multiple birthmarks, Down syndrome, congenital heart defects, and gastrointestinal anomalies. Similarly, birth defects were reported more often among index case patients with AML than among control subjects and included a significant increase in multiple birthmarks, Down syndrome, mental retardation, and congenital heart defects. Exclusion of patients with Down syndrome from the analysis did not change the statistically significant excess of gastrointestinal anomalies in patients with ALL or the excess of birthmarks in patients with AML. However, the majority of the observed associations with congenital anomalies occurred in children with Down syndrome.

In a study of 20,029 children with cancer in England between 1971 and 1986, the occurrence of congenital anomalies was significantly lower in children with leukemia or lymphoma (2.6%) than in children with solid cancers (4.4%).[334] This finding is compatible with the hypothesis that mutations leading to the development of leukemias and lymphomas occur at a much later stage in development in the cells committed to hematopoiesis.

Birth Weight and Length at Birth

Birth weight might serve as an indirect indicator of the intrauterine stresses to the fetus and therefore has been studied by numerous investigators for its association with leukemia.[§] The accumulating literature on high birth weight and risk of childhood ALL, particularly at younger ages, is becoming increasingly convincing as demonstrated in a meta-analysis.[340] High levels of insulin-like growth factor–1, which might both produce a larger baby and contribute to leukemogenesis, has been postulated as an explanation for this association.[341] No consistent association has been reported between length of child at birth and leukemia.[152,321]

Vitamin K

Several studies have explored the association between vitamin K administered in the neonatal period and leukemia, with inconsistent results.[148,342-347] The initial studies by Golding and associates[342,343] from England showed an association between intramuscularly (but not orally) administered vitamin K and childhood leukemia. The biologic basis for the association between vitamin K and childhood leukemia was the observation that concentrations of vitamin K in the infants 12 to 24 hours after injection have been shown to increase sister chromatid exchanges in human placental lymphocytes in vitro and sheep fetal lymphocytes in vitro.[348] However, in vivo studies in human neonates did not substantiate this observation.[349] Moreover, the positive association between leukemia of all types and vitamin K reported by Golding and associates has not been confirmed by analytic studies in England,[346] Germany,[345] Denmark,[350] Sweden[344] and the United States.[351] Parker and associates[352] reported a positive association between parenterally administered vitamin K and childhood ALL diagnosed between the ages of 1 and 6 years, although no association was seen in a cohort-based study. The authors stated that a definite conclusion regarding the relationship between vitamin K and childhood leukemia has not yet been reached. Thus the relationship between vitamin K and childhood leukemia is tenuous at best and the attributable risk is extremely small, with some as yet unidentifiable biologic predisposition placing the patients at increased risk of the development of childhood leukemia.[353]

FUTURE DIRECTIONS

The occurrence of cancer during childhood remains one of the leading causes of childhood mortality, even with the marked improvements in the treatment and cure of pediatric malignancies during the past three to four decades. Although the volume of epidemiologic research addressing the cause of childhood cancer is considerable, relatively little has been achieved regarding our understanding of the cause of childhood leukemia, which would have direct impact on potential future prevention strategies. The absence of progress is not the result of a lack of research in populations around the world directed toward investigation of environmental and genetic factors. This body of research includes large case-control epidemiologic studies including thousands of pediatric leukemia cases, with many incorporating state-of-the-art clinical and biological characterization of cases along with environmental sampling designed to enhance exposure assessment. Future research in this, the most common malignancy of childhood, will probably need to focus on patients with a common primary genetic lesion, such as those with BRC-ABL, MML-AF4, or ETV6-RUNX1 fusion, or hyperdiploidy. By investigating within such well-defined groups, the potential exists to identify common environmental and genetic factors that result in the specific genetic lesion.

12. Kinlen LJ, Petridou E: Childhood leukemia and rural population movements: Greece, Italy, and other countries. *Cancer Causes Control* 6:445–450, 1995.

    The infection hypothesis was tested by examining the impact of major rural-urban migration on mortality from childhood leukemia in the 1950s and 1960s—an era that preceded the decline in mortality brought about by effective chemotherapy. Greece and Italy, the two countries with the most striking levels of rural migration, also had the highest mortality rates from childhood leukemia, suggesting that marked rural population mixing in Greece and Italy may have contributed to their high mortality rates from childhood leukemia in the 1950s and 1960s.

13. Greaves MF, Alexander FE: An infectious etiology for common acute lymphoblastic leukemia in childhood? *Leukemia* 7:349–360, 1993.

    Epidemiologic data, reviewed in this article, indicate that risk of B-cell precursor, a form of ALL (cALL), is increased among persons with higher socioeconomic status, isolation, and other characteristics suggestive of abnormal patterns of infection during infancy. The authors conclude that these data may be compatible with the concept that cALL may be a rare response to common infection(s).

17. Bhatia S, Sather HN, Heerema NA, et al: Racial and ethnic differences in survival of children with acute lymphoblastic leukemia. *Blood* 100:1957–1964, 2002.

    African-American and Hispanic children with ALL who were treated with Children's Cancer Group protocols had worse outcomes and Asian children had better outcomes when compared with non-Hispanic white children. The poorer outcomes among black children were most apparent among patients with standard-risk features, whereas poorer outcomes in Hispanic children were most evident among patients with high-risk features. Asian children had better outcomes than all racial and ethnic groups among high-risk patients, particularly in the recent era.

61. Shannon K: Genetic predispositions and childhood cancer. *Environ Health Perspect* 106(Suppl 3):801–806, 1998.

    The role of genetic susceptibility in childhood cancer is discussed, with a particular emphasis on problems with ascertaining inherited cancer risk and the role of tumor-suppressor gene mutations in cancer predispositions. The association between

neurofibromatosis type 1 and childhood leukemia is used to illustrate issues related to identifying and analyzing at-risk persons.

62. Zipursky A, Poon A, Doyle J: Leukemia in Down syndrome: a review. *Pediatr Hematol Oncol* 9:139–149, 1992.

The authors use observations from their own experience, reports in the literature, and data accumulated in the Canadian Down Syndrome Leukemia Registry to describe the epidemiologic and clinical characteristics of leukemia in children with Down syndrome.

71. Merks JH, Caron HN, Hennekam RC: High incidence of malformation syndromes in a series of 1,073 children with cancer. *Am J Med Genet A* 134A:132–143, 2005.

The authors describe the prevalence and nature of malformation syndromes associated with childhood cancer in 1073 children with cancer. They observe that the prevalence of patients with a proven or suspected syndrome is high, suggesting a possible association.

72. Narod SA, Stiller C, Lenoir GM: An estimate of the heritable fraction of childhood cancer. *Br J Cancer* 63:993–999, 1991.

The authors reviewed the records of the 16,564 cases of childhood cancer diagnosed from 1971 to 1983 that were reported to the National Registry of Childhood Tumours in Great Britain to estimate the proportion that results from inherited mutations. The total genetic fraction was estimated to be 4.2%.

80. Buckley JD, Buckley CM, Breslow NE, et al: Concordance for childhood cancer in twins. *Med Pediatr Oncol* 26:223–229, 1996.

The authors of this study determined the concordance rates for childhood cancer in twins to clarify the importance of constitutional predisposition. The monozygotic casewise concordance rate was 5%. The results suggest that a strong constitutional genetic component for childhood cancers other than retinoblastoma does not exist.

84. Ford AM, Ridge SA, Cabrera ME, et al: In utero rearrangements in the trithorax-related oncogene in infant leukaemias. *Nature* 363:358–360, 1993.

This report describes three pairs of infant twins with concordant leukemia who each share unique but nonconstitutive HRX rearrangements in their leukemic cells, demonstrating that the leukemogenic event originates in utero and provides support for intraplacental "metastasis" for leukemia concordance in twins.

102. Taylor GM, Dearden S, Ravetto P, et al: Genetic susceptibility to childhood common acute lymphoblastic leukaemia is associated with polymorphic peptide-binding pocket profiles in HLA-DPB1*0201. *Hum Mol Genet* 11:1585–1597, 2002.

*This study demonstrates an association between childhood cALL and an allele at the HLA-DPB1 locus, DPB1*0201, pointing to a mechanism of cALL susceptibility that involves the presentation of specific antigenic peptides, possibly derived from infectious agents, by DPbeta1*0201–related allotypic proteins and leading to the activation of helper T cells, mediating proliferative stress on preleukemic cells.*

103. Wiemels JL, Smith RN, Taylor GM, et al: Methylenetetrahydrofolate reductase (MTHFR) polymorphisms and risk of molecularly defined subtypes of childhood acute leukemia. *Proc Natl Acad Sci U S A* 98:4004–4009, 2001.

This study examines the role for alterations in folate metabolism as a result of polymorphisms in the enzyme methylenetetrahydrofolate reductase (MTHFR) in the risk of three subgroups of pediatric leukemias: infant leukemias with MLL *rearrangements and childhood lymphoblastic leukemias with either ETV6-RUNX1 fusions or hyperdiploid karyotypes. Carriers of C677T demonstrated protection from leukemias with* MLL *translocations. A1298C homozygotes and C677T homozygotes offer protection from hyperdiploid leukemia, providing preliminary evidence for a role of folate in the development of childhood leukemia.*

117. Ford AM, Bennett CA, Price CM, et al: Fetal origins of the TEL-AML1 fusion gene in identical twins with leukemia. *Proc Natl Acad Sci U S A* 95:4584–4588, 1998.

The ETV6-RUNX1 genomic sequence has been characterized in a pair of monozygotic twins with common ALL diagnosed at ages 3 years, 6 months and 4 years, 10 months. The twin leukemic DNA shared the same ETV6-RUNX1 fusion sequence, suggesting a single cell origin of the TEL-AML fusion in one fetus in utero, probably as a leukemia-initiating mutation, followed by intraplacental metastasis of clonal progeny to the other twin.

118. Wiemels JL, Ford AM, Van Wering ER, et al: Protracted and variable latency of acute lymphoblastic leukemia after TEL-AML1 gene fusion in utero. *Blood* 94:1057–1062, 1999.

This study describes the natural history of disease in a pair of identical twins with concordant ALL separated temporally by 9 years. The genomic fusion sequence was identical in the two leukemias, indicative of a single cell origin in one fetus, in utero. These data suggest that consequent to a prenatal initiation of a leukemic clone, most probably by TEL-AML fusion, the latency of ALL can be protracted.

119. Gale KB, Ford AM, Repp R, et al: Backtracking leukemia to birth: identification of clonotypic gene fusion sequences in neonatal blood spots. *Proc Natl Acad Sci U S A* 94:13950–13954, 1997.

121. Raynaud S, Cave H, Baens M, et al: The 12;21 translocation involving TEL and deletion of the other TEL allele: two frequently associated alterations found in childhood acute lymphoblastic leukemia. *Blood* 87:2891–2899, 1996.

122. Hong D, Gupta R, Ancliff P, et al: Initiating and cancer-propagating cells in TEL-AML1-associated childhood leukemia. *Science* 319:336–339, 2008.

This study explores the clonal evolution of ETV6-RUNX1 ALL. A cell compartment in leukemic children that can propagate leukemia when transplanted in mice is identified. The study suggests that ETV6-RUNX1 functions as a first-hit mutation by endowing preleukemic cells with altered self-renewal and survival properties.

125. Greaves MF, Wiemels J: Origins of chromosome translocations in childhood leukaemia. *Nat Rev Cancer* 3:639–649, 2003.

This commentary describes the etiopathogenesis of leukemia by describing the timing of the occurrence of chromosome translocations and discussing the role of these genetic changes as necessary but not usually sufficient to cause leukemia.

126. Kinlen LJ: Epidemiologic evidence for an infective basis in childhood leukaemia. *Br J Cancer* 71:1–5, 1995.

This review provides a broad overview for the infectious etiology for childhood ALL.

135. Kinlen LJ, O'Brien F, Clarke K, et al: Rural population mixing and childhood leukaemia: effects of the North Sea oil industry in Scotland, including the area near Dounreay nuclear site. *BMJ* 306:743–748, 1993.

This study demonstrates a significant excess of leukemia and non-Hodgkin lymphoma in 1979-1983 in the group of rural home areas with the largest proportion of oil workers, following closely after large increases in the workforce, supporting the infection hypothesis that population mixing can increase the incidence of childhood leukemia in rural areas.

209. Murray R, Heckel P, Hempelmann LH: Leukemia in children exposed to ionizing radiation. *N Engl J Med* 261:585–589, 1959.

This article provides evidence for the observed increased risk of leukemia among children with a prior history of exposure to ionizing radiation reported by Stewart, Webb, and Hewitt. These findings are placed in the context of studies describing the experience of the Japanese inhabitants in Hiroshima and Nagasaki at the time of nuclear explosions, patients who have ankylosing spondylitis, children treated in infancy for enlargement of the thymus gland, and American radiologists.

230. Petridou E, Trichopoulos D, Dessypris N, et al: Infant leukaemia after in utero exposure to radiation from Chernobyl. *Nature* 382:352–353, 1996.

Infants exposed in utero to ionizing radiation from the Chernobyl accident had 2.6 times the incidence of leukemia compared with unexposed children; those born to mothers residing in regions with high radioactive fallout were at higher risk of developing infant leukemia. No significant difference in leukemia incidence was found among children aged 12 to 47 months. Preconception irradiation had no impact on leukemia risk.

279. Savitz DA, Wachtel H, Barnes FA, et al: Case-control study of childhood cancer and exposure to 60-Hz magnetic fields. *Am J Epidemiol* 128:21–38, 1988.

This study was one of the first to examine the impact of extremely low frequency magnetic fields (e.g., proximity to electric power distribution lines) on the risk of childhood cancer. Exposure was characterized through in-home electric and magnetic field measurements under low and high power use conditions and wire configuration codes, a surrogate measure of long-term magnetic field levels. Measured magnetic fields under low power use (and not under high power use) conditions had a modest association with cancer incidence. Wire codes associated with higher magnetic fields were more common among case than control homes.

287. Linet MS, Hatch EE, Kleinerman RA, et al: Residential exposure to magnetic fields and acute lymphoblastic leukemia in children. *N Engl J Med* 337:1–7, 1997.

This study investigated the impact of measuring a single home and then imputing information from another home among subjects who lived in two homes in a subset of an investigation of residential exposure to magnetic fields and risk of childhood leukemia. All methods with measurements from one of the homes in conjunction with imputation of measurements for the second home led to attenuation of risk estimates. These results provided little evidence to support a risk of electric and magnetic field and cautioned against attempting to estimate lifetime magnetic field exposure from imputed values derived from current residences to fill in gaps caused by unmeasured residences previously lived in.

302. Ross JA, Potter JD, Reaman GH, et al: Maternal exposure to potential inhibitors of DNA topoisomerase II and infant leukemia (United States): a report from the Children's Cancer Group. *Cancer Causes Control* 7:581–590, 1996.

This study tested the hypothesis that de novo infant leukemias (with MLL *gene rearrangements commonly associated with topoisomerase II inhibitors) may occur as a result of maternal exposure to agents in diet and medications that inhibit DNA topoisomerase II. No significant trends for ALL were found with increasing maternal consumption. However, a statistically significant positive association was found between AML and increasing consumption of foods containing DNA topoisomerase II inhibitors.*

315. Mucci LA, Granath F, Cnattingius S: Maternal smoking and childhood leukemia and lymphoma risk among 1,440,542 Swedish children. *Cancer Epidemiol Biomarkers Prev* 13:1528–1533, 2004.

In this investigation, population-based registries in Sweden were used to examine maternal smoking during pregnancy and childhood risk of leukemia. Maternal smoking was associated with a lower risk of ALL but a higher risk of AML.

322. Westergaard T, Andersen PK, Pedersen JB, et al: Birth characteristics, sibling patterns, and acute leukemia risk in childhood: a population-based cohort study. *J Natl Cancer Inst* 89:939–947, 1997.

In this population-based record linkage study, a direct association between birth weight and childhood leukemia was observed. In addition, a weak inverse association between birth order and ALL risk was observed among children younger than 5 years.

336. McLaughlin CC, Baptiste MS, Schymura MJ, et al: Birth weight, maternal weight and childhood leukaemia. *Br J Cancer* 94:1738–1744, 2006.

This case-cohort study reports increased risk of ALL associated with birth weight of 3500 g or more, as well as evidence of effect modification with birth weight and maternal prepregnancy weight. High birth weight was associated with ALL only when the mother was not overweight, and heavier maternal weight was associated with ALL only when the infant did not have a high birth weight. Increased pregnancy-related weight gain was associated with ALL.

Gene Set Enrichment Analysis
CONCLUSIONS

The first genome to be sequenced came at a cost of $100 million. Only 13 years later, the price for sequencing an entire genome is nearing $1000 (Fig. 41-1). Rapid increases in the speed and complexity of genomic sequencing technologies, coupled with dramatically decreasing costs, have created an overwhelming array of platforms, methods, and informatics analysis algorithms. In many publications the authors assume the reader is facile with the platform used in the study described, yet most clinicians and researchers have a limited or narrow knowledge of the wide range of methods capable of describing the genomic or proteomic content of a biologic sample. This chapter focuses on describing the basic framework with which to understand most of the common platforms in use today.

Genomic platforms can be classified in many ways, and one can consider the starting material (e.g., deoxyribonucleic acid [DNA], ribonucleic acid [RNA], proteins, and small molecules) or the questions being asked (e.g., copy number, mutations, loss of heterozygosity [LOH], transcript expression, and methylation). The classification scheme shown in Table 41-1[1,2] classifies each platform according to the underlying structure, and the remainder of this chapter is organized in this fashion.

DNA-BASED METHODS

Most of the time the goal of studying DNA is to learn about the genes encoded, including mutations, rearrangements, and changes in copy number. Low-resolution methods prevailed for years as the standard way of understanding copy number variations and rearrangements (e.g., karyotyping and fluorescent in situ hybridization [FISH]), and low-throughput techniques were required to evaluate point mutations and pathogenic sequences (e.g., capillary sequencing, pyrosequencing, polymerase chain reaction [PCR], and microbial arrays). The emergence of high-throughput, high-resolution techniques has revolutionized the study of the genome.

Comparative Genomic Hybridization

Until the development of comparative genomic hybridization (CGH), chromosomal or subchromosomal gains and losses were discovered though Giemsa banding ("karyotyping") or FISH. Although similar in resolution to these techniques (5 to 10 megabases[3]), CGH can be used in an unbiased and agnostic way to detect unbalanced chromosomal abnormalities by competitive FISH using different fluorophores for two different isolates of DNA (e.g., test and control).[4-6] The technique was also

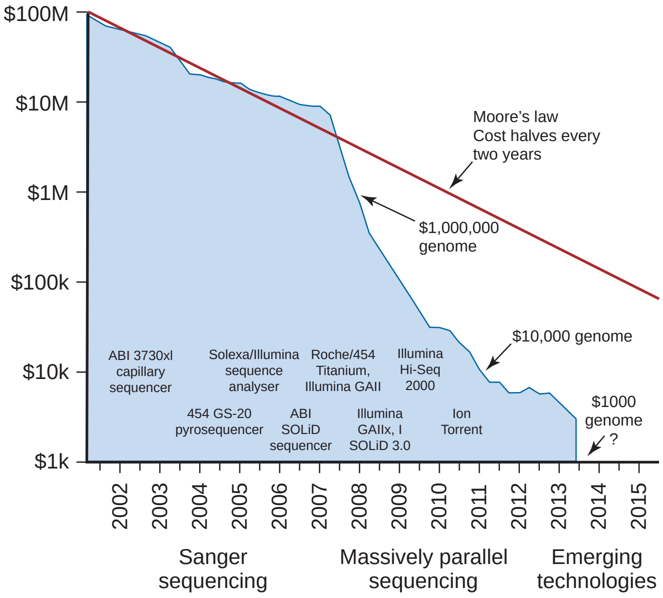

Figure 41-1 The decreasing cost of genome sequencing. Note that the price has been falling faster than Moore's law would predict. *(Modified from MacConaill LE: Existing and emerging technologies for tumor genomic profiling.* J Clin Oncol *31:1815–1824, and Mardis ER: Next-generation DNA sequencing methods.* Annu Rev Genomics Hum Genet *9:387–402, 2008.)*

novel because it did not require cells to be undergoing active cellular division.[7] With the popularization of DNA microarrays, a higher resolution technique was developed: array CGH (aCGH).[8-10] As is common to all microarray techniques, probes (oligonucleotides) are deposited onto a solid support (glass slide), with the resolution dependent on the size of the probes and the genomic distance separating them.[11] DNA from a test sample and control are extracted, labeled with different fluorescent dyes, and applied to the probes (Fig. 41-2). Complementary strands will bind and can be visualized with use of a digital imaging system to quantify the relative amounts of each target bound. The ratio of test to control for each DNA region can then be used to determine copy number variation throughout the genome. Compared with prior methods, aCGH can detect copy number changes at any locus, as long as it is represented in the array. The technique has been productively applied to the study of thousands of diseases and complex traits, and despite the emergence of newer high-resolution methods, aCGH continues to be a significant platform for the study of copy numbers.

Genotyping

Genotyping is simply determining the genetic variation in an individual. Many methods may be used to perform genotyping with varying degrees of throughput. Restriction fragment length polymorphism analysis was productively applied to describe human leukocyte antigen polymorphisms, followed by PCR-based methods using membrane- or bead-bound sequence-specific oligonucleotide probes and sequence-specific priming (reviewed in references 12 and 13).[12,13] For the specific application of identifying a point mutation or allelic variant, genotyping via PCR followed by restriction digestion is a simple approach that has been applied to many diseases and conditions, including fatty acid binding protein mutations in insulin resistance[14,15] and identification of polymorphisms in thiopurine methyltransferase in leukemia[16] and methylenetetrahydrofolate reductase in childhood acute leukemia.[16]

Capillary (Sanger) Sequencing

Sanger sequencing, which was first developed in 1977, has been routinely used for more than 25 years for genomic studies.[17,18] In the classic method (Fig. 41-3), chain-terminating nucleotides are incorporated by DNA polymerase during DNA replication with a synthesized primer specific to the region of interest. Compared with normal deoxynucleoside triphosphates, terminating dideoxynucleoside triphosphates lack a 3′-hydroxyl group, and DNA polymerase is unable to create the phosphodiester bond between two nucleotides, thus halting transcription. Four DNA replication samples are prepared, each with a different radiolabeled or fluorescently tagged dideoxynucleoside triphosphate, and the resulting DNA products are separated by electrophoresis and visualized by autoradiography or ultraviolet light. Current instruments use dye terminators instead of fluorescent labels, resulting in faster and more accurate readings.[19,20] The relatively high cost for reagents and the nonautomated nature of traditional Sanger sequencing have been largely obviated by the development of microfluidic technology.[21-24] All of the steps for Sanger sequencing are carried out on a small chip using nanoliter volumes. This "lab-on-a-chip" or "sequencing-on-a-chip" technique increases speed and accuracy while decreasing costs. Despite limited resolving power for the first 25 to 50 bases and read lengths fewer than 1000 bases, Sanger sequencing is still being used for smaller scale projects or when a long contiguous read is desired.

Pyrosequencing

In pyrosequencing, liberated pyrophosphates from nucleotide incorporation are detected and the DNA sequence is determined by light emitted upon nucleotide incorporation.[25-28] Because only one nucleotide at a time is presented to the DNA template and DNA polymerase, the base responsible for the emitted light is the one incorporated into the growing strand. The pyrophosphate release during the reaction is converted to adenosine triphosphate, fueling a luciferase-based fluorescent reaction. Although the reads are shorter (300 to 500 base pair [bp]), multiple reactions can be detected simultaneously, thereby increasing throughput.

DNA Microarrays

A microarray is simply a small piece of DNA (the "probe") that is attached to a solid support, which is usually a glass, plastic, or silicon chip (e.g., an Affymetrix [Santa Clara, CA] genome chip, gene array, or DNA chip) or polystyrene beads (Illumina, San Diego, CA). The process of "printing" the array refers to the deposition of the DNA onto the solid support, either through "spotting"

TABLE 41-1 Types of "-omics" Data

Underlying Structure	"-omics"	Alterations in Disease	Technologies

(complementary DNA [cDNA] microarray[29]) or by synthesizing the oligonucleotides directly onto the array surface.[30-32] For a spotted array, the probes are produced beforehand, either through the production of a cDNA library, by PCR, or by the generation of oligonucleotides that are then "spotted" directly onto the support surface, often by a robot.[33,34,35]

Single Nucleotide Polymorphism Arrays

A single nucleotide polymorphism (SNP) is any sequence variation in the genome for which both alleles occur at a relatively high frequency. The vast majority do not appear to confer functional consequences.[36] Although they are located most often in noncoding regions, SNPs can occur

anywhere throughout the genome. More than 50 million SNPs have been cataloged in the SNP database.[37] High-density SNP arrays can be used for genetic linkage studies to map disease loci and complex traits.[38,39] Because SNP arrays can detect slight differences between individual genomes, the polymorphisms detected can be used to characterize disease susceptibility or drug effectiveness.[40,41] A comparison of intensities of DNA-bound SNP probes can be used to determine the relative DNA copy number for a given locus based on the SNP map.[42] A specific application of SNP arrays is in detection of LOH in tumors and other malignancies (Fig. 41-4).[43-46] When examining paired blood and tumor samples, SNPs detected as heterozygous in blood and homozygous in tumor (LOH) may be part of a region where a normal copy of a tumor suppressor gene was lost. A special case of LOH called uniparental disomy is a copy-neutral gene conversion.[47-49] Instead of a deletion leading to the loss of the normal allele, a nondisjunction event results in LOH without a change in copy number. Although undetectable by FISH or karyotyping, this important type of LOH can be inferred from an SNP virtual karyotype.

Chromatin Immunoprecipitation, ChIP-Chip, ChIP-Seq

Chromatin immunoprecipitation (ChIP) is used to investigate the interaction between proteins and DNA. In addition to defining the locations of transcription factor binding, ChIP can also aid in determining the location of histone modifications.[50-52] The basic concepts for all ChIP studies are similar (Fig. 41-5). Proteins are cross-linked to DNA, and the cell is lysed. The protein-bound DNA is sheared, and immunoprecipitation is used to “pull down” the protein-bound DNA regions of interest.[53] The DNA is then isolated and purified, and different

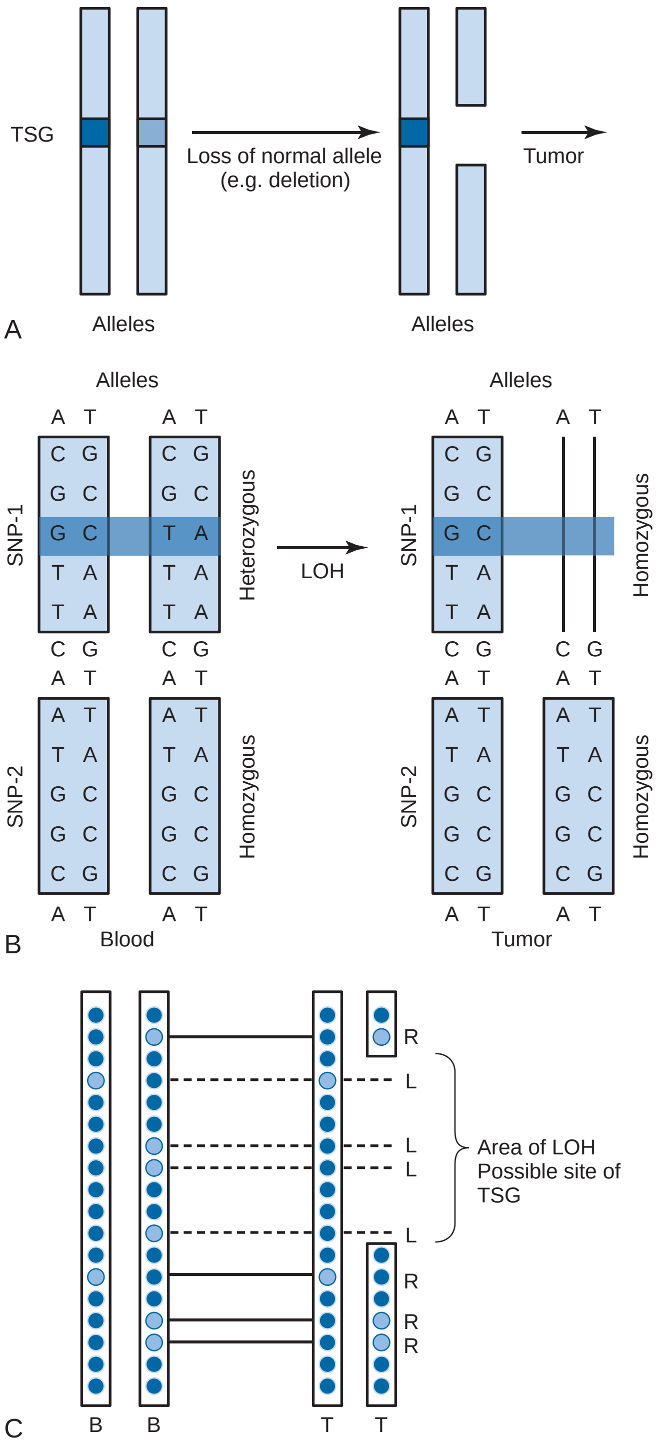

Figure 41-4 Using single nucleotide polymorphism *(SNP)* array technology to detect loss of heterozygosity (LOH) with detection of a possible tumor suppressor gene *(TSG)*. **A,** Part of a chromosome with a mutated *(black)* and normal *(gray)* copy of a TSG. Loss of the normal TSG leads to tumor formation, because the remaining TSG is not functional. **B,** Region of chromosome from blood and tumor showing two SNPs. The subject is homozygous for SNP-2 in the blood but heterozygous for SNP-1. In the tumor sample from the same patient, SNP-1 is detected as homozygous, because one of the alleles has been lost. This "loss of heterozygosity" can be a marker for chromosomal deletion. **C,** An expanded view of both alleles showing many SNPs. In the tumor, several of the heterozygous SNPs have been lost, indicating the site of a possible TSG. Homozygous SNPs are noninformative, because the loss of an allele will not be detected.

techniques are used to determine the sequence and region of DNA bound by the protein. In standard ChIP, low-resolution, traditional sequencing methods[54] or PCR are used, followed by genome mapping. ChIP has been productively applied to study histone binding,[55,56] histone acetylation,[57] and cell differentiation in myeloid leukemia cells.[58] To increase the coverage and depth of DNA binding site discovery, the analysis of protein-bound DNA was extended to DNA microarrays ("ChIP-chip" or "ChIP-on-chip").[59-61] This technique has been applied to describe histone binding patterns,[62,63] identify therapeutic targets in persons with acute myelogenous leukemia,[64] and describe and map transcriptional networks and histone modifications in leukemia.[65,66] With the development and popularization of next-generation sequencing (NGS) techniques, the products of ChIP can be subjected to high-resolution sequencing ("ChIP-seq"). This technique has been used to describe a genome-wide map of chromatin binding in stem cells,[67] delineate histone phosphorylation,[68] identify transcription factor binding sites,[69] demonstrate the requirement of histone ligase in mixed-lineage leukemia–rearranged leukemia,[70] describe transcriptional networks,[65] and provide overall maps of chromatin binding and histone modifications in leukemia.[66]

Genome-Wide Association Studies

The purpose of a genome-wide association study (GWAS) is typically to compare two groups (e.g., cases/control) to find common genetic variants associated with either group.[71-73] As a by-product of sequencing the human genome, the discovery of large numbers of SNP variants facilitated an unbiased interrogation of the genome. Useful SNPs must be selectively neutral and have relatively high frequencies (generally >0.05). More than 1 million SNPs were collected for the HapMap project, capturing most of the genomic variation in a select number of human populations.[74] GWA studies are only dependent on linkage disequilibrium between the genotyped SNP and the nongenotyped causal variants, with the strength of the association depending on their allele frequencies (Fig. 41-6). Hundreds of loci have been discovered for many complex diseases and traits such as Crohn disease,[75] ulcerative colitis,[76] and short stature.[77] Metabolic traits, autoimmune diseases, cancer, and many complex traits have been studied extensively and with large sample sizes by GWA studies.[77a] Data from a GWA study are typically visualized with use of a Manhattan plot (Fig. 41-7).[78] Much of the statistical analysis of GWA study data focuses on determining the significance threshold given the sample size and the large number of features (multiple testing).[79]

Exome Sequencing/Targeted Sequencing

Although GWA studies have identified many loci contributing to diseases and complex traits, most findings account for only a small proportion of the heritability.[80,81] Many mendelian disorders have been attributed to underlying genetic changes through linkage analysis and resequencing. Nevertheless, the causative mutations for more than half of the ~6000 known mendelian disorders remain

Figure 41-5 Chromatin immunoprecipitation *(ChIP)* is used to determine the deoxyribonucleic acid *(DNA)* sequences bound to proteins of interest. In traditional ChIP *(left)*, proteins are cross-linked to DNA, the cells are lysed, and the DNA is sheared. Immunoprecipitation is used to pull down the protein-DNA complexes. Purified DNA is then subjected to sequencing through traditional methods with mapping to the genome. In ChIP-chip (ChIP-on-chip), the DNA is not sequenced but is instead labeled and applied to a DNA array. By applying differentially labeled input DNA, the regions to which the proteins were bound can be ascertained. Most recently, high-resolution sequencing (ChIP-seq) techniques have emerged in which the isolated and purified DNA is subjected to high-resolution next-generation sequencing. *PCR,* Polymerase chain reaction.

unknown, mostly because of the paucity of cases and low penetrance.[82-84] Therefore an abundance of low-penetrant common variants are now described that reportedly contribute to the inheritance of common diseases (Fig. 41-8).[85] Highly penetrant but rare mutations that contribute to diseases with mendelian inheritance are being identified through NGS high-throughput methods that parallelize the sequencing process, producing millions of concurrent sequences.[86-89,90-92] To better focus on these potential causes of disease, target enrichment strategies were developed to facilitate a focused sequencing to determine the coding variation in the entire genome (Fig. 41-9).[93,94] The exome represents the 1% of the genome (30 megabases) that is translated into proteins.[95] Although the untranslated regions are part of the exon, exome sequencing studies usually do not include these regions. The general workflow for whole exome sequencing (WES) involves DNA extraction, fragmentation, exome segment isolation, and sequencing (Fig. 41-10).[96] For many diseases for which conventional approaches have failed,

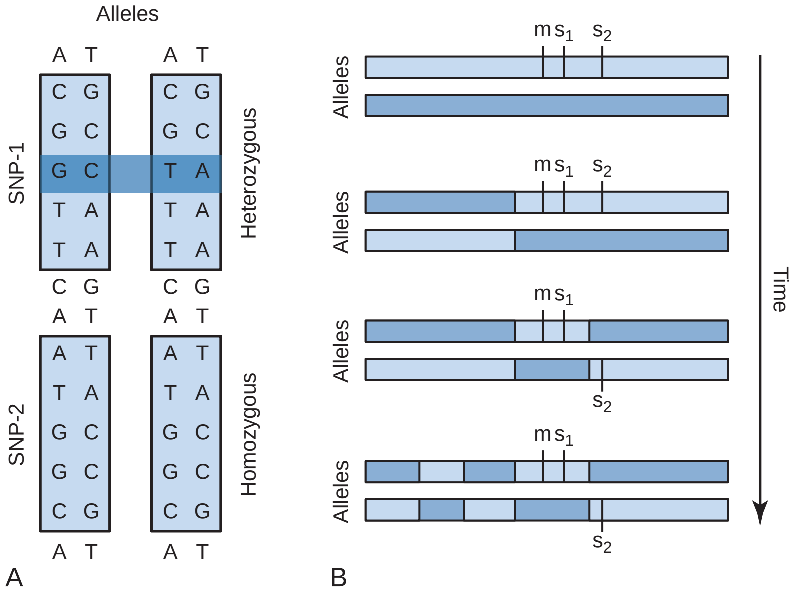

Figure 41-6 **A,** Two single nucleotide polymorphisms *(SNPs)* are shown, both on the same chromosome. This individual is heterozygous for SNP-1 and homozygous for SNP-2. **B,** A gene mutation is shown, along with two SNPs. The first SNP is closely associated with the mutation, whereas the second is in strong linage disequilibrium. Note how during recombination, the haplotype block containing the mutation and SNP-1 remains intact, whereas SNP-2 does not remain associated. By comparing large numbers of SNPs in persons with a disease to persons without a disease, one can infer the location of mutations associated with the condition.

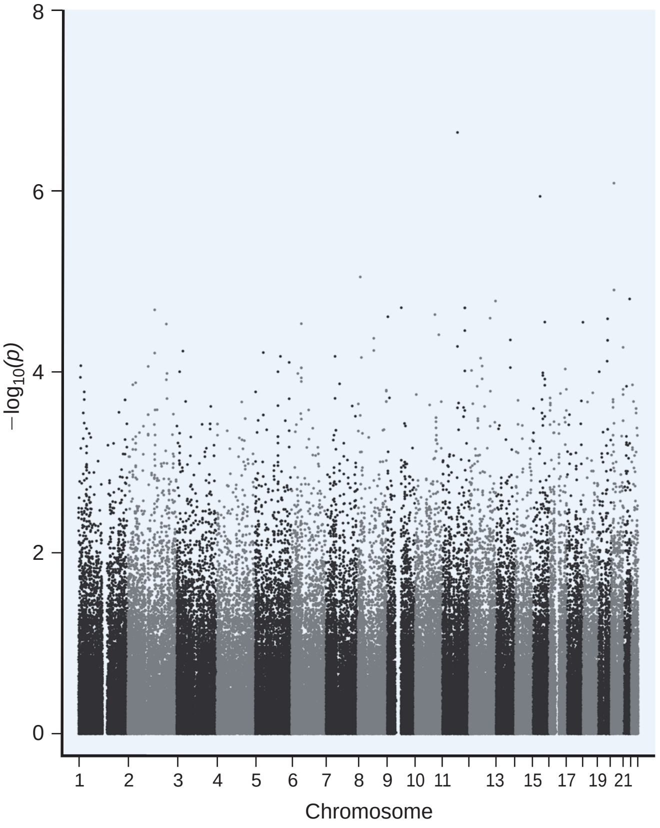

Figure 41-7 A typical Manhattan plot showing the significance of genetic variants (single nucleotide polymorphisms) along each chromosome. The highest ones are most likely to be statistically significant.

exome sequencing has led to candidate gene identification.[97,98,99,100] Targeted exome sequencing has also provided evidence for alternative transcriptional start sites in colorectal carcinoma,[101] RET gene fusion in lung cancer in nonsmokers,[102] and stage-specific alternative splicing in neuroblastoma.[103] Of course, identifying the disease-related genes among all of the sequencing errors and non–disease-causing polymorphisms remains a considerable challenge. The application of exome sequencing typically results in identification of more than 20,000 single nucleotide variants, and although most are known polymorphisms, other details are necessary, such as the pedigree, mode of inheritance, and sample size. The informatics techniques for identifying causal and alternatively spliced variants are well established.[97,104-106] Although the costs of whole genome sequencing (WGS) are decreasing, WES remains a mainstay for identifying causal variants of genetic diseases.

Whole Genome Sequencing

NGS methodologies can be applied to determine the entire sequence of an organism's genome. A current role for WGS and WES is to study whether common complex diseases are driven by rare variants ("rare variant hypothesis")[107-109] or by many common variants with small effects on risk ("common disease–common variant").[110-112] Methods for WGS are similar to exome and whole transcriptome sequencing (Fig. 41-10). Isolated and fragmented DNA is subjected to repetitive and overlapping sequencing to achieve the most robust coverage. Although the cost of WGS remains relatively high, identification of rare disease-causing variants is often achieved by family studies in which sequencing efforts are focused on individuals at the extremes of the trait's

Conversely, mendelian diseases are characterized by being rare but highly penetrant. Many interesting findings will fall in the middle range with modest variant frequency with moderate penetrance. *(Modified from McCarthy MI, Abecasis GR, Cardon LR, et al: Genome-wide association studies for complex traits: consensus, uncertainty and challenges.* Nat Rev Genet *9:356–369, 2008, and Eeles R, Goh C, Castro E, et al: The genetic epidemiology of prostate cancer and its clinical implications.* Nat Rev Urol *11:18–31, 2014.)*

distribution or by studying the most distant coaffected subjects.[109] As might be expected, considerable informatics challenges exist for determining significant rare variants.[113]

RNA-BASED METHODS

Whole Transcriptome Shotgun Sequencing (RNA-Seq)

Although hybridization-based (e.g., microarray) studies target the millions of common alleles (SNPs) in the genome, such libraries are limited in their ability to detect rare variants that cause disease. NGS methodologies facilitate the unbiased sequencing of all RNA transcripts in a cell (RNA-seq[114,115]; Fig. 41-9), providing a means to study gene fusions,[116] mutations, alternative splicing,[117-119] and modulation in gene expression levels.[120-124] Subpopulations of RNA such as microRNA (miRNA), transfer RNA, and ribosomes can be characterized as well.[125-129] Sequencing of the transcriptome has been applied to many malignancies, including prostate cancer,[130] mesothelioma,[131] squamous cell lung cancer,[132] Fanconi anemia,[133] and breast cancer.[134] The general workflow for transcriptome sequencing is similar to WGS and WES, except that isolated RNA must first be converted into a cDNA library (Fig. 41-10). Once sequencing data have been collected, alignment and contig generation depend on the presence of a scaffold for a known genome or de novo methods for a novel genome.[114,135-137]

Expression Profiling

By measuring the activity of thousands of genes simultaneously, it is possible to make broad global assessments of cellular activity or compare expression levels of genes between two different states or conditions.[35,138] The development and commercialization of DNA microarrays have commoditized the analysis of gene expression, making it a common method of study of biologic systems. The general process is similar to other microarray-based workflows (Fig. 41-11). Commercial systems (e.g., Affymetrix GeneChip and Illumina BeadArray) utilize oligonucleotide arrays of varying density, depending on the application. The target sample is prepared by extracting miRNA, creating cDNA using reverse transcriptase,

and then labeling the DNA. Even though each chip characterizes a single sample, the high reproducibility of the system facilitates comparison of expression levels between more than one condition. To compare two conditions directly, they are first differentially labeled (e.g., green and red), combined, and then applied to a cDNA array with subsequent measurement of the intensity ratios.[139] Three applications for gene expression profiling are: (1) class comparison, (2) class prediction, and (3) class discovery.[138] For class comparison, the objective is to understand which genes are differentially expressed between two known disease subtypes or conditions (Fig. 41-12).[140] The goal of class prediction is to define a classifier that can facilitate class membership for a sample based on its gene expression profile.[141-143,144-146] Class discovery is useful when trying to define clinically relevant molecular subtypes.[140,146-150] MiRNA functions as a regulator of gene expression both during and after transcription.[151] The expression of miRNA can be monitored with use of microarrays, as described earlier.[152,153] Such methods were used to show a novel miRNA profile for chronic lymphocytic leukemia.[154-156]

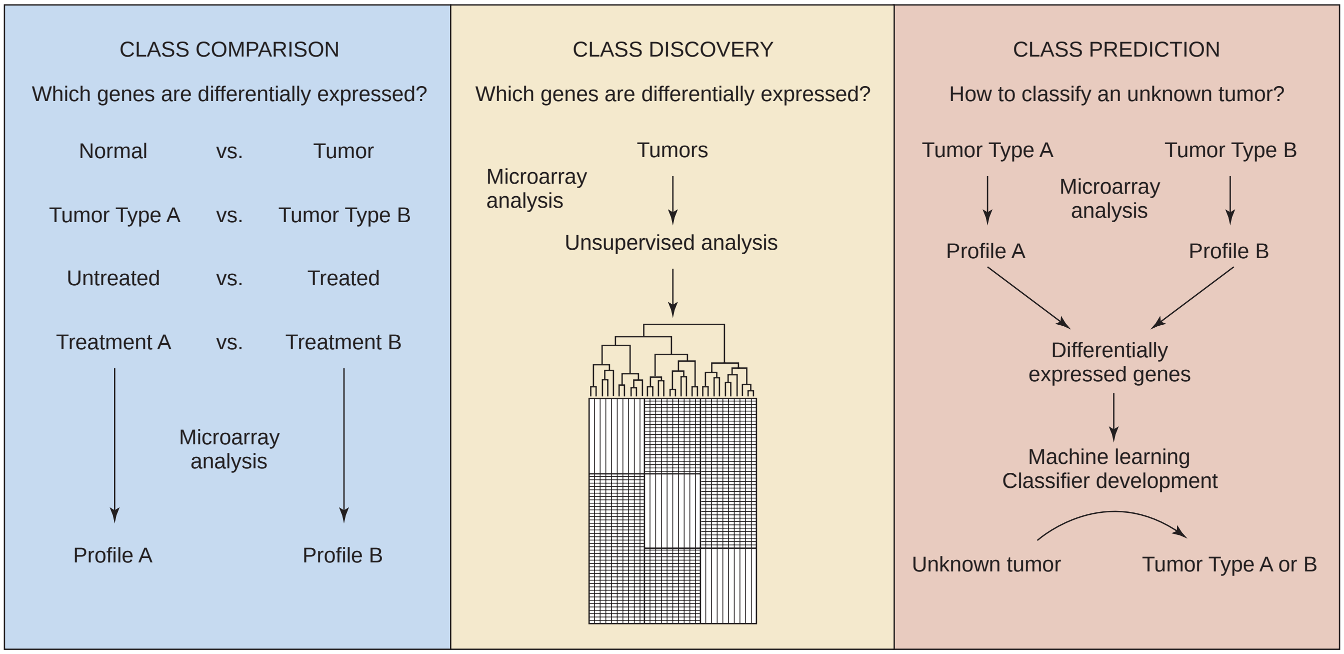
PROTEIN-BASED METHODS

Protein Microarrays

The large-scale monitoring of protein expression, function determination, and interaction can be assessed through the use of protein microarrays. Similar to DNA microarrays in concept, proteins are immobilized on the surface of a solid support, such as a glass slide.[157,158] Protein probes labeled with fluorescent dye are applied to the array and the interactions are monitored by laser scanning. Protein microarrays have been used to construct interactome maps,[159] monitor protein levels in patients with chronic graft-versus-host disease,[160] and facilitate biomarker identification for cancer and other diseases.[161-164]

Mass Spectrometry

Proteomic analysis by mass spectrometry (MS) remains the mainstay of comprehensive protein analysis in cells and other complex systems. In general, most MS-based studies follow a paradigm of protein isolation, enzymatic digestion, separation, MS, and informatic analysis (Fig. 41-13).[165] For quantitative studies,[166] cells can be grown in differential isotopic media (with stable isotope labeling by amino acids in culture) or labeled during or after enzymatic digestion (oxygen-18 [18O],[167] isobaric tag for relative and absolute quantitation [iTRAQ][168]) so that amounts of nonlabeled (light) and labeled (heavy) peptides can be compared. Traditional proteomic approaches involving data-dependent acquisition are based on selecting the top most abundant precursor ions for fragmentation. As a result, protein identifications are disproportionate, with the abundant proteins in a sample



CLASS COMPARISON
Which genes are differentially expressed?

Tumor Type A or B

Figure 41-12 Applications for gene profiling include class comparison *(left)* in which two different conditions or tumors are compared to determine which genes are differentially expressed. Class discovery *(middle)* does not require prior knowledge about the tumor types but instead looks for subgroups of differentially expressed genes. Class prediction *(right)* results in the discovery of a gene classifier that can predict the class of an unknown sample.

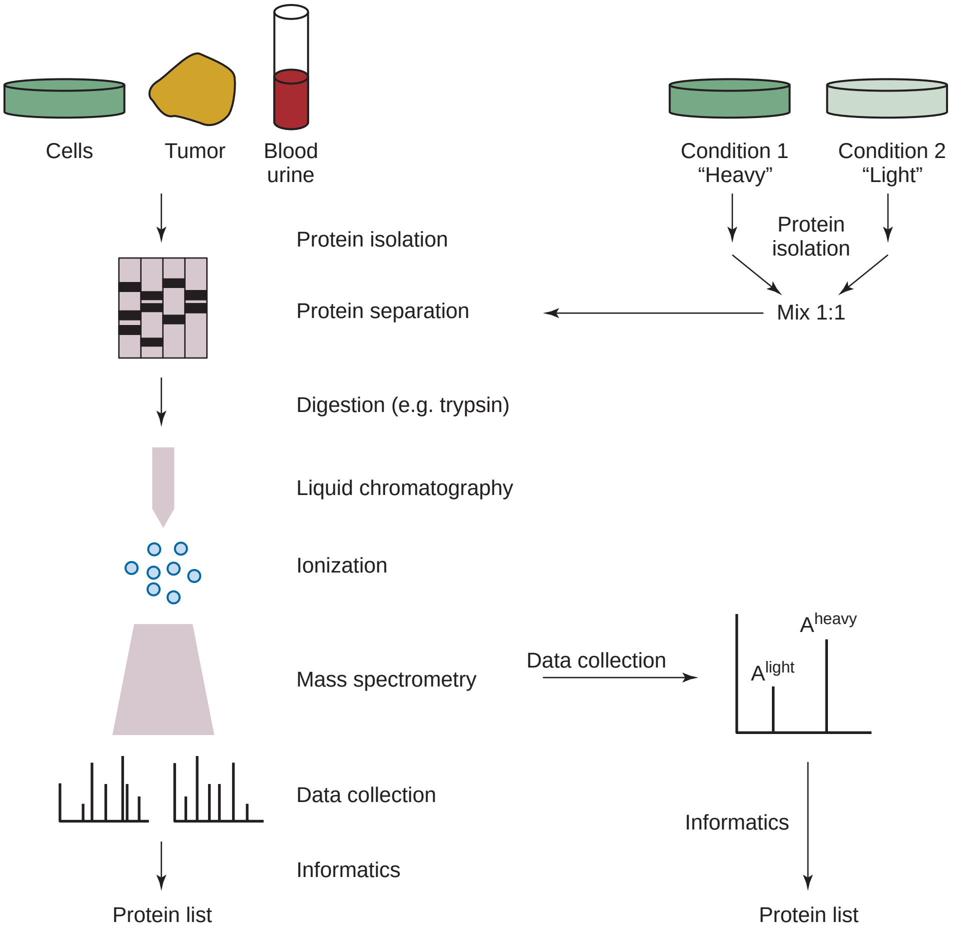

Figure 41-13 The standard workflow for mass spectrometry–based proteomics *(left)* includes isolation of proteins from a complex sample followed by separation, usually by gel electrophoresis. The proteins are then subjected to trypsin digestion and then separated by liquid chromatography prior to ionization and injection onto the mass spectrometer. All data are collected and then analyzed offline to match spectra to peptides and to create the most parsimonious protein list. A quantitative proteomics experiment *(right)* often involves growing cells in a "light" (normal) and "heavy" isotope-labeled media. The proteins are then mixed in equal amounts and subjected to a similar workflow. Peptides from each condition can be identified by the characteristic mass shift, and their relative peak heights correspond to quantitative differences.

getting more coverage and low-abundance (and often more interesting) proteins being missed entirely. The downside of narrow dynamic range is evident in MS analysis of complex samples such as human serum, wherein the most abundant proteins account for more than 85% to 90% of total protein content,[169,170] whereas the more informative proteins remain in the low molecular weight serum proteome.[171-173] To circumvent these issues, researchers typically incorporate the use of labeled cell lines, enrichment strategies, fractionation techniques, and protein depletion methods (e.g., Agilent [Santa Clara, Calif.] Multiple Affinity Removal System column) into experimental protocols.[171,174] On the analysis front, inclusion lists and single/multiple reaction monitoring assays for targeted proteomics are used and have been shown to be sensitive[175,176] even in the context of biomarker validation in human plasma.[177,178] However, these methods still have a fundamental flaw in that the candidates for inclusion are chosen without regard for the overlap between the proteins of interest and the dominant background. Thus, in the context of analyzing important cancer protein markers, the complexity of the human proteome makes it difficult for the MS platform to characterize a few select proteins effectively. Informatics challenges present a second major obstacle to the effective use of proteomics in a clinical setting. Providing researchers and clinicians with access to powerful computing resources and data management tools that are capable of rapidly processing the hundreds of samples in large-scale clinical settings remains a challenge. Existing proteomics pipelines such as the Trans-Proteomic Pipeline,[179] OpenMS,[180] and ProteoWizard[181,182] run on workstations but do not work effectively at these scales. On-demand cloud computing services, such as that operated by Amazon Web Services, provide an intriguing alternative,[183] and cloud-based options for data processing are available.[184-186] Galaxy-P (https://usegalaxyp.org/), developed at the University of Minnesota, is a framework for performing computation-intensive proteomic data processing on their computer cluster. Inspired by the public Galaxy server[187,188] that is used for genomics at the University of Pennsylvania, Galaxy-P offers key proteomics software applications on a freely available platform.

INFORMATICS

A full summary of the informatics tools and techniques across the broad spectrum of platforms and methods discussed is beyond the scope of this review. Nevertheless, it is important to understand a few fundamental concepts when evaluating genomic data. With the popularization and wide availability of tools for genomic data analysis, it is common for research groups to perform their own analysis despite little or no experience in bioinformatics and statistics. However, the interpretation of complex and dense data is subject to many caveats and pitfalls. The algorithms for class comparison, discovery, and prediction all require specialized knowledge for proper application. The general procedure for analysis of microarray data includes background correction, normalization, logarithmic transformation, batch effect correction, outlier removal, and probe filtering.[189-193] Each of these steps has many variations, and understanding the indications and caveats for each is an important part of data analysis.

False-Positive Rate, Sample Size, and Validation

With a large number of features, the number of false-positive results becomes significant. For instance, when testing 20,000 genes for differential expression, even if none is truly significant (i.e., no true-positives), a traditional false-positive rate of 5% would indicate that 1000 genes will be falsely classified as differentially expressed. One possible approach is simply to increase the stringency by ranking the genes by *P* value and testing the value for significance based on 5% multiplied by the rank of the *P* value divided by the number of features, thus limiting the false-discovery rate to less than 5%. A simpler method is the Bonferroni correction, in which the *P* value is divided by the number of tests.[194] The most important factors influencing the *P* value are the absolute proportion of true-positive differentially expressed genes, the distribution of the differences, the variability in expression, and the sample size.[195] Of course, overly aggressive methods for controlling for the false-discovery rate will raise the false-negative rate. Increasing the sample size can help alleviate this problem.[195,196] It is critical that differentially expressed genes be validated, either in another experiment using a different sample set or by using an alternative method such as reverse transcriptase–PCR.[196]

Clustering and Classification

Classification is the process of predicting membership in predetermined groups and requires training data with known class assignments for each point.[197] For example, with a set of gene expression data on patients with leukemia of known risk group status, one could use classification techniques to predict which features (genes) could be used to classify an unknown patient. Classification is a form of supervised learning and requires knowledge of not only the feature values (gene expression) but also the class of each sample. Supervised learning methods are usually neighbor based, such as k-nearest neighbors, or based on discriminating hyperplanes, such as linear discriminant analysis, neural networks, and support vector machines.[198,199] In clustering analysis, no predefined classification is required. Instead, the classification is to be learned from the data only, because the algorithms divide the data into natural groups based on intrinsic properties only. A common unsupervised method is principal component analysis, which is particularly useful for microarray expression data where many intracorrelations exist between a large number of the variables.[200,201] Transforming the original high-dimensional data into a lower dimensional space retains the intrinsic critical information while still facilitating a meaningful separation of the samples into relevant groups. Hierarchical clustering is another form of unsupervised analysis, which is commonly visualized through heat maps.[197]

Gene Set Enrichment Analysis

After using statistical analyses with gene expression data, it may still be difficult to extract useful meaning from the data. For instance, after correction for multiple hypotheses testing, few or no genes may be found to be differentially expressed. Alternatively, the list of differentially expressed genes may appear to have no underlying biologic theme. Additionally, the overall effect of pathway interactions may be masked as a result of the measurement of one gene at a time. One way to compensate for these shortcomings is to apply gene set enrichment analysis to the data.[202] The strategy in gene set enrichment analysis is to use predefined knowledge of gene pathways to evaluate microarray data at the level of the gene set. This process is a means of identifying functionally related groups of genes.[203]

CONCLUSIONS

It remains challenging to keep pace with the rapid advancements in systems biology technology. The development and widespread adoption of NGS technologies have resulted in torrents of data. The informatics challenges are considerable and include issues of storage, access, and analysis. These problems will only continue to grow because the rate of data accumulation is likely to increase. As more institutions adopt genomic testing platforms, informaticists, geneticists, pathologists, and other clinicians will need to work together to apply these tools appropriately.[204] With the concurrent popularization and widespread availability of genomics analysis tools, it is increasingly important to retain expertise in the acquisition and analysis of high-density genomic data. Many successful research institutions have established bioinformatics core service teams that serve as collaborators throughout the experimental process, from planning to data collection to analysis and interpretation. Bioinformatics experts are most likely to have access to the most current and advanced tools and will understand the subtleties and nuances inherent to complex data analysis and interpretation. For the nonexpert, it is most important to understand the context in which the technology or platform is being used. As old methods are supplanted by new ones, the most well-informed scientist, researcher, or clinician will recognize the progression and adoption of newer technologies and appreciate any positive and negative implications. We have never experienced a more exciting time in medicine. In the next 10 years, enormous growth will occur in our knowledge about complex biological processes, resulting in new methods of disease prevention and therapy.

CHAPTER 42

Genetic Predisposition to Cancer

Kristin Zelley, Robert B. Lindell, Joshua D. Schiffman, and Kim E. Nichols

CHAPTER OUTLINE

PRINCIPLES OF CANCER PREDISPOSITION
IDENTIFICATION OF A CHILD WITH A CONDITION PREDISPOSING TO CANCER
- Features of Family History Suggestive of a Heritable Predisposition to Cancer
- Tumor Features Suggestive of a Heritable Predisposition to Cancer
- Other Clinical Features Suggestive of a Heritable Predisposition to Cancer

CONCLUSIONS, CHALLENGES, AND LOOKING TO THE FUTURE

It is currently estimated that 1% to 10% of children with cancer develop the disease due to an underlying genetic predisposition.[1-4] Over the last 3 decades, there has been an explosion in knowledge regarding the heritable causes of cancer, including the discovery of many genes that when mutated in the germline significantly increase the risk for tumor formation in children. This knowledge has allowed for a better understanding of the mechanisms leading to tumor formation and provided insights into the development of novel cancer therapies targeting defective genetic pathways. Through presymptomatic genetic testing, it is also now possible to identify children who are at increased risk for tumor formation and to initiate surveillance protocols with the intent to improve overall outcomes through the detection of early-stage tumors that are more readily cured with less invasive and/or toxic therapies. In this chapter, we review the principles of cancer predisposition, steps involved in the recognition and testing of children for heritable cancer syndromes, and concepts underlying tumor surveillance. We also describe the clinical and genetic features typifying specific syndromes and review current recommendations regarding management. As there are too many conditions to discuss in this chapter, we focus on several syndromes that are associated primarily with the development of solid tumors. For a review of additional childhood cancer syndromes, including those that increase the risk for hematologic malignant tumors, we refer the reader to several excellent recent reviews.[5-8]

PRINCIPLES OF CANCER PREDISPOSITION

Seminal insights into cancer predisposition were gained in 1971 when Alfred Knudson developed the *two-hit hypothesis* to explain the epidemiology of retinoblastoma (RB), the most common pediatric eye tumor.[9] Children with RB show two patterns of tumor formation, including: (1) early-onset disease characterized by bilateral eye involvement and autosomal dominant inheritance; or (2) later-onset disease typified by unilateral eye involvement with no family history of RB. According to the two-hit hypothesis, children with bilateral RB are at increased risk for tumor formation because they carry an altered copy of a growth regulatory gene within the cells of the body; this constitutional (germline) mutation is known as the first hit. Knudson proposed that if the second gene copy underwent an inactivating mutation within a developing retinal cell (i.e., the second hit), that cell would then become susceptible to tumor formation. Because every cell in a child with heritable RB carries the first hit, children with this form are likely to develop more than one tumor (multifocal and/or bilateral RB) at a very young age. In contrast, for those with nonheritable RB, both hits would need to occur within a single retinal cell. As these mutational events are exceedingly rare, it is expected that the process would take longer and be less likely to occur. Thus, children with nonheritable RB would be older at presentation and only develop unilateral tumors.

In 1986, Stephen Friend confirmed Knudson's prediction by demonstrating that patients with bilateral RB harbor inactivating germline mutations in the RB susceptibility gene *RB1*, the first tumor suppressor gene to be identified.[10] Since this initial observation, many additional tumor suppressor genes have been cloned, and it is now clear that inactivating tumor suppressor gene mutations account for the majority of heritable cancers in humans. Other genetic mechanisms that contribute to heritable cancers include the presence of constitutional activating or "gain-of-function" mutations involving one copy of a growth-promoting oncogene, inactivating mutations in one or both alleles of an X-linked or autosomal recessive gene, and larger structural chromosomal abnormalities such as translocations, deletions, and duplications that disrupt or enhance the expression of a tumor suppressor gene or oncogene, respectively.

IDENTIFICATION OF A CHILD WITH A CONDITION PREDISPOSING TO CANCER

Pediatric oncologists play an important role in recognizing hereditary cancer syndromes in children and their families. Toward this end, there are several possible clues that point to the existence of a condition that predisposes a child to cancer, including: (1) a positive family history of cancer; (2) the diagnosis of specific tumor types in the child; (3) tumors that involve paired organs; and (4) the presence of associated physical or syndromic features. Pediatric oncologists should consider each of these factors when evaluating a patient and refer the child to a geneticist or genetic counselor when there is a suspicion of an underlying cancer predisposition.

Features of Family History Suggestive of a Heritable Predisposition to Cancer

Features of the family history that are suggestive of a genetic predisposition to cancer include the presence in the child or his or her close relatives of one or more cancers presenting at a younger than expected age, involving both of paired organs (e.g., eyes, kidneys, or adrenal glands) or exhibiting multifocality (more than one discrete tumor within an organ). Other suspicious features include the existence of multiple individuals on the same side of the family (maternal or paternal lineage) with the same type of cancer or cancers known to cluster together in certain syndromes (e.g., the clustering of soft tissue and bone sarcomas, early-onset breast cancer, brain tumors, adrenocortical cancers, and leukemia in Li-Fraumeni syndrome [LFS]).

Pediatricians and pediatric oncologists should take a careful family history and generate a pedigree as a routine part of each patient's initial clinic visit. Ideally, the pedigree should include information about the child being seen (the proband), as well as his or her first-degree relatives (parents and siblings), second-degree relatives (aunts, uncles, and grandparents), and third-degree relatives (first cousins). For any individuals who have developed a cancer, its type, site of origin, stage (laterality, focality), and the age at which it was diagnosed should be determined. It is important to note whether individuals have had more than one cancer, and if so, to distinguish whether multiple cancers represent recurrence of the initial tumor or development of a second primary malignant tumor. Finally, it is important to gather information about the ethnic background of the family, as some genetic syndromes manifest more commonly in individuals from specific geographic regions (as is the case with hereditary breast and ovarian cancer, which is more common in Ashkenazi Jewish individuals with ancestors from Eastern Europe). Information about the biologic relationship between parents can provide insights into the mode of inheritance. For example, if parents are closely related or both come from a similar geographic region, there is a greater chance for consanguinity and the presence of an autosomal recessive condition.

The importance of collecting a family history cannot be underestimated; however, this procedure can have its limitations. Some hereditary syndromes exhibit incomplete penetrance where not everyone with the inherited mutation will develop a cancer. Variable expressivity can be a complicating factor, with affected individuals manifesting in different ways within a given family. One must recognize that family histories evolve over time. A child may have an affected parent; however, this parent might be young or not yet have developed a cancer or other features typical of the condition. In some cases, affected family members may die of other causes before they develop a cancer. Finally, the family history may be unrevealing when there is a de novo germline mutation in an affected child, the presence of autosomal recessive or X-linked recessive conditions (where carriers are clinically unaffected), nonpaternity, or situations in which a child is adopted and there is little knowledge of the biologic parents' family history. Due to these factors, it may be difficult to ascertain from a pedigree whether a specific syndrome is present. Nonetheless, the family history remains an important tool in recognizing conditions predisposing a child to cancer, and one should be obtained, regularly updated, and reviewed for the presence of a possible predisposition.

Tumor Features Suggestive of a Heritable Predisposition to Cancer

In addition to whether the tumor is unilateral or bilateral, unifocal or multifocal, specific tumor types should raise the suspicion of a syndrome predisposing to cancer, even in the absence of a positive family cancer history (Table 42-1). RB is an excellent example as there is a hereditable

†Several other leukemia predisposition syndromes exist that are not discussed here.

component in 40% of patients.[11,12] Additional tumor types associated with a high likelihood of an underlying genetic predisposition include: (1) Wilms tumor (WT), where features such as bilaterality, early age of onset, and genitourinary anomalies in boys indicate a higher likelihood of a germline *WT1* mutation[13,14]; (2) pheochromocytoma (PCC) and paraganglioma (PGL), where more than 70% carry a germline mutation in *SDHB* or other associated PCC/PGL genes[15,16]; (3) atypical teratoid/rhabdoid tumor, where 35% carry a mutation in the *INI1/SMARCB1* gene[17]; (4) pleuropulmonary blastoma (PPB), where more than 70% of cases in one study carried a germline *DICER1* mutation[18]; (5) hepatoblastoma (HB), where up to 10% carry a mutation in the *APC* gene that is causative of familial adenomatous polyposis (FAP)[19]; (6) medullary thyroid cancer (MTC), where 20% to 25% carry a mutation in the *RET* protooncogene[20]; (7) medulloblastoma, where onset at an age younger than 5 years and desmoplastic histology are indicative of possible nevoid basal cell carcinoma syndrome (NBCCS, Gorlin syndrome)[21,22], where patients harbor germline mutations of *PTCH1*; and (8) adrenocortical carcinoma (ACC), choroid plexus carcinoma (CPC), and rhabdomyosarcoma presenting under the age of 3 years, where 50% to 80%, 35% to 100%, and 20% of children, respectively, carry germline mutations in the *TP53* gene.[23-27] The diagnosis of an adult-onset tumor in a child should also raise suspicion for a predisposing condition. For example, the presence of colorectal cancer could indicate a constitutional mismatch repair–deficiency (CMMR-D).[28-30]

Other Clinical Features Suggestive of a Heritable Predisposition to Cancer

Specific clinical features can provide clues to the diagnosis of an underlying cancer predisposition. These features include physical findings, cognitive or developmental disabilities, and the presence of benign tumors (Table 42-2). Primary physicians and pediatric oncologists should be alert to the presence of these manifestations in their patients. If suspicion of a hereditary cancer syndrome is raised, the child should be referred to a geneticist or genetic counselor, as well as appropriate specialist(s) for evaluation, genetic testing, and management.

Dermatologic Findings

Benign or malignant skin findings are a common feature of several cancer predisposition syndromes, and evaluation by a dermatologist may be helpful in characterizing these findings and facilitating the diagnosis. Café-au-lait macules and axillary and inguinal freckling are a well-known example and are crucial in establishing a clinical diagnosis of neurofibromatosis type 1 (NF1)[15,31] (Fig. 42-1). Café-au-lait macules are often the earliest clinical manifestation of NF1, as they are present in 99% of affected children by 1 year of age.[32] Café-au-lait macules are also a cardinal feature of CMMR-D.[33,34] Skin pigmentation differences may also provide a clue to the diagnosis of PTEN hamartoma tumor syndrome (PHTS). For example, boys with PHTS may exhibit pigmented macules of the glans penis, which should raise the suspicion of the diagnosis, especially if features such as macrocephaly, developmental delay, or autism are present. Other skin findings are also found in PHTS, including trichilemmomas and papillomatous papules; however, these may not be diagnosed until later in life.[35] Individuals with Peutz-Jeghers syndrome (PJS) commonly exhibit mucocutaneous pigmentation resembling “freckling” around the mouth, eyes, or nostrils, or on the buccal mucosa or perianal area. Skin cancers in children may also indicate the presence of a syndrome predisposing to cancer. NBCCS predisposes individuals to basal cell carcinomas, which generally appear in the late teens or early adult years, but can occasionally develop in young children. Benign skin findings such as palmar and plantar pits and facial milia may be present in individuals with NBCCS.[36]

TABLE 42-2 Clinical Manifestations of Syndromes Predisposing to Cancer

Manifestation	Predisposition Syndrome	Gene(s)
Cutaneous		
Café-au-lait macules	Neurofibromatosis type 1 (NF1)	*NF1*
	Constitutional mismatch repair–deficiency syndrome (CMMR-D)	*MLH1, MSH2, MSH6, PMS2*
Axillary or inguinal freckling	NF1	*NF1*
Penile freckling	PTEN hamartoma tumor syndrome (PHTS)	*PTEN*
Mucosal pigmentation	Peutz-Jeghers syndrome (PJS)	*STK11*

Seizures	NF1	*NF1*
	NF2	*NF2*

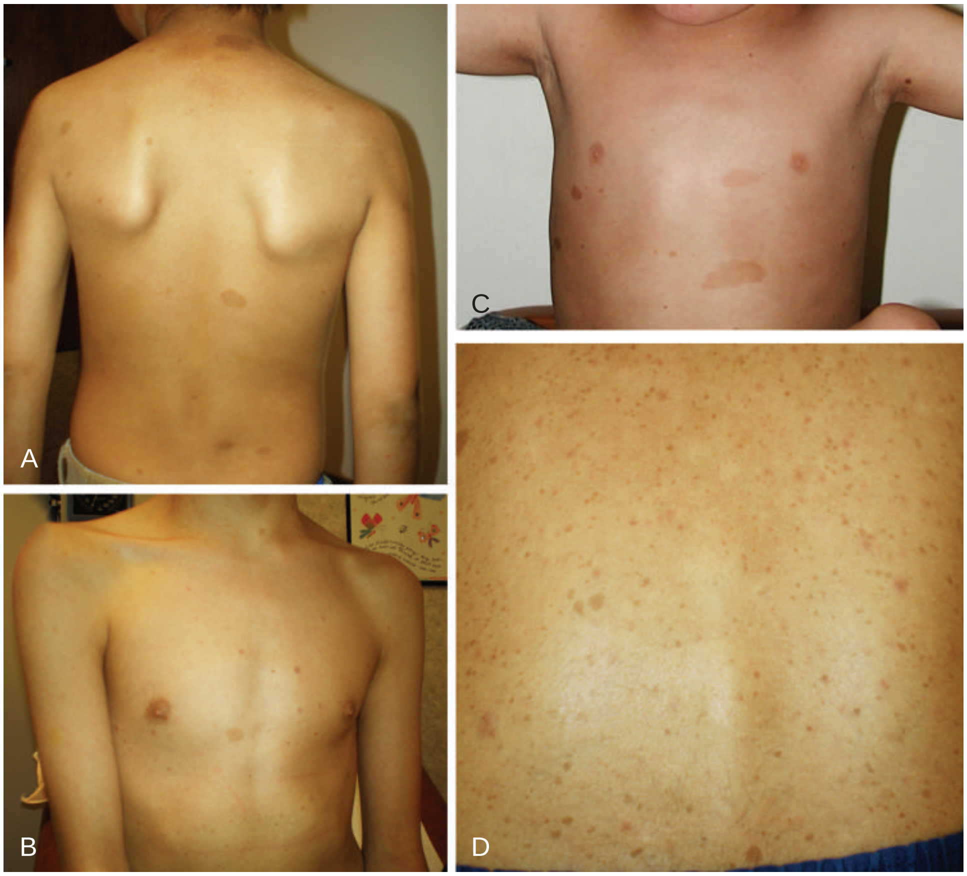

Figure 42-1 Café-au-lait spots in neurofibromatosis type 1 (NF1). (**A** to **D**). Photographs depicting the appearance of typical café-au-lait spots, as seen in NF1. Café-au-lait spots exhibit distinct edges and are slightly darker than the surrounding skin. Café-au-lait spots can increase in size, number, and darkness throughout childhood. Multiple café-au-lait spots alone are not a definitive indication for NF1; they must be present with other established criteria in order to make the diagnosis. In (**C**), there is also evidence of bilateral axillary freckling.

Developmental or Cognitive Abnormalities

Developmental or cognitive disabilities, including delays in achieving motor milestones, intellectual disabilities, and autism-spectrum disorders are commonly seen in cancer predisposition syndromes, including PHTS; WT, aniridia, genitourinary malformations, and retardation (WAGR) syndrome; tuberous sclerosis; 13q deletion syndrome (which predisposes to RB); and NF1. Seizures may also be a feature, where they are often seen in NF1 and tuberous sclerosis, and may indicate the presence of an underlying tumor. Any child with cancer who has a history of developmental or intellectual disabilities, autism-spectrum disorders, seizures, and/or other neurologic features should be considered a candidate for referral for a possible cancer genetics evaluation.

Overgrowth

Generalized or focal overgrowth of specific parts of the body can be a feature of a condition predisposing to cancer, such as Beckwith-Wiedemann syndrome (BWS), PHTS, and Simpson Golabi Behmel syndrome. In BWS overgrowth may manifest with generalized macrosomia at birth, and some patients may also exhibit macroglossia and/or asymmetric overgrowth of one side of the body (hemihypertrophy). Hemihypertrophy may involve the extremities or external physical features (face, labia, buttocks), as well as internal organs (where, for example, one kidney may be larger than the other). Macrosomia is also a feature of Simpson Golabi Behmel syndrome and Proteus syndrome (PS), while macrocephaly can be a manifestation of PHTS and NBCCS.

Specific Congenital Anomalies

In some cases, the presence of specific congenital anomalies can serve as an early indicator of a condition predisposing to cancer. For example, an omphalocele or umbilical hernia, especially in a child with macrosomia, macroglossia, ear pits or creases, or neonatal hypoglycemia, can point to the diagnosis of BWS. Another good example is WAGR syndrome, where affected children have aniridia, often in combination with genitourinary abnormalities such as hypospadias or cryptorchidism.

Other Physical Features

Other physical manifestations may also suggest an underlying hereditary cancer syndrome. Examples include individuals with multiple endocrine neoplasia type 2B (MEN2B), who often present with mucosal neuromas of the lips and tongue, ganglioneuromas, and marfanoid habitus, and those with FAP, who may present with dental abnormalities (missing or extra teeth), epidermal cysts or pilomatrixomas, Gardner fibromas (also known as desmoid tumors), osteomas (usually involving the jaws), and congenital hypertrophy of the retinal pigmented epithelium. Generally these manifestations present prior to the development of colon polyps.

Incidental Identification of a Child with a Condition Predisposing to Cancer

Until recently, genetic testing for hereditary cancer syndromes was only offered when an individual presented with a specific cancer type, physical or developmental features consistent with a known syndrome predisposing to cancer, or a suggestive family history. Due to the increasing use of genome-wide approaches to establish a genetic diagnosis, including single-nucleotide polymorphism arrays, multigene panels, and whole-exome sequencing, the "incidental" discovery of a gene mutation that predisposes to cancer is becoming more and more common. This information can lead to the unintended diagnosis of a predisposing syndrome prior to its clinical manifestation in the child and/or his or her family. Toward this end, several recent studies of genome-wide microarrays have reported the identification of copy number variations involving genes predisposing to cancer in individuals presenting with a noncancer phenotype.[37-39] In these studies, the frequency of incidental findings involving genes predisposing to cancer was estimated to be between 0.18% and 0.60%.[40-42]

The testing of tumor samples for somatic genetic mutations is also being pursued with the intent of facilitating "personalized" cancer care by identifying and therapeutically targeting mutated genetic pathways in tumors. When evaluating tumors, it is often necessary to compare tumor-derived sequences to those obtained using normal tissue from the same individual. As a result, it is possible to identify incidental constitutional mutations that are indicative of an underlying cancer predisposition or other nononcologic condition.[43,44] In one recent study, most patients undergoing tumor genetic testing expressed interest in receiving incidental germline genetic test results, as most thought this information would be valuable to family members. However, some perceived it to be an additional burden on top of their cancer diagnosis.[45] Many laboratories have specific policies regarding the sequencing of normal tissue and return of incidental results. Therefore, prior to ordering tumor testing, pediatric oncologists should be familiar with the performing laboratory's policy, discuss the possibility of obtaining incidental genetic findings with the patient and his or her parents, and determine whether or not they would like to receive these results as part of the informed-consent process.

Genetic Testing for a Heritable Predisposition to Cancer

Complexities of Childhood Cancer Genetic Testing

Genetic testing for cancer predisposition is a complex process that should be explored with the patient and family, preferably by a genetic counselor or trained genetics professional, prior to performing the testing. Counseling should include information about the natural history of the condition under consideration, methods of testing and its possible outcomes, as well as the potential risks, benefits, and limitations of testing. Patients may have concerns about privacy, confidentiality, insurance coverage, and genetic discrimination, all of which must be addressed. For the oncologist, it is important to recognize that genetic test results have implications not only for the individual being tested but also for his or her family members. This factor necessitates counseling of the whole family and discussion of how the results will be communicated between various members. When the individual under consideration is a minor (defined here as a person <18 years), the importance of these issues is further magnified by the fact that children generally do not have the capacity to fully understand the risks, benefits, and limitations of genetic testing. Therefore, they are not able to make their own informed decisions about whether or not to be tested. Instead, this decision falls to the child's parent(s) or guardian(s), and strips the child of the opportunity to make an autonomous decision about genetic testing later in life. Testing in childhood and disclosure of results to parents, guardians, and/or other family members may violate the child's privacy, confidentiality, and right not to know.[46,47,48] Many also fear that performing genetic testing on a child may have adverse psychological consequences, such as depression, anxiety, fear of the future, altered self-image, limited horizons (i.e., impact on thoughts about future education and career choices), and altered family relationships.[49] However, others have argued for the possible benefits of genetic testing in childhood, such as relief if test results are negative, providing certainty about genetic risk, and allowing the child to integrate genetic information into the self-concept at a younger age, when it is less disruptive to the sense of self. Until recently, the concerns about testing children have more or less superseded the possible benefits of such testing.

Despite much debate, available evidence suggests that the negative consequences of cancer genetic testing may be fewer and less severe than anticipated. Studies of the psychosocial consequences of genetic testing in adults have generally shown minimal or no negative consequences and suggested that emotional outcomes may be more dependent on factors such as pretest emotional state and social support than on the actual genetic test result itself.[50,51] Several studies report that adults undergoing genetic testing for LFS consider obtaining certainty about cancer risk a psychological benefit of testing, even if adults are found to be affected.[51,52] Data on the outcomes of presymptomatic cancer genetic testing of children are more limited. Much of the data comes from testing for FAP, where affected individuals are prone to develop multiple gastrointestinal polyps, which if left untreated invariably lead to early-onset colorectal cancer. In FAP, polyps generally begin to form during adolescence. Consequently, it is recommended that children begin surveillance with colonoscopy around the age of 10 to 12 years. Based on these factors, it is deemed appropriate to offer

FAP genetic testing to minors. Published reports describing the psychosocial consequences of pediatric FAP genetic testing reveal that children by and large do not experience significant distress related to this testing.[53,54,55] One report describing the psychological outcomes of genetic testing of minors for LFS did not note any significant negative outcomes after up to 12 years of follow-up.[56] However, in this study, the participation rate in testing for minors was low, with only 4 of 26 parents who were offered testing for their children actually following through with the test. Therefore, it remains to be determined whether and how genetic testing for these or other conditions predisposing to cancer impacts the well-being of children and their families.

Guidelines for Testing Children for a Heritable Predisposition to Cancer

The controversies surrounding genetic testing of children have prompted several groups to issue guidelines and recommendations. Most recommendations indicate that the primary justification for presymptomatic (i.e., predictive) genetic testing is medical benefit for the child. Therefore, testing should be offered to minors only if the condition is known to manifest in childhood and there are effective preventive or therapeutic interventions available. Conversely, if cancer risk is not increased in childhood or if there are not effective surveillance or intervention measures, it is recommended that testing be delayed until adulthood, when a child can then independently decide whether or not to pursue the testing. Families must be counseled about the benefits, risks, and limitations of genetic testing in order to give informed consent for genetic testing on behalf of their child. As with other medical interventions, it is the role of the health care provider to advocate for the best interests of the child when discussing the option of genetic testing. If possible, minors should be encouraged to participate in decision making about genetic testing; however, the capacity of children to understand genetic information is variable and depends upon their age, maturity, education, and cognitive abilities. Disclosure of results to tested minors is also encouraged once the minor reaches the legal age of majority, or possibly sooner if it is felt that the minor is capable of understanding and coping with the results.[49,56-61,62]

Management of Children with a Heritable Predisposition to Cancer

The identification of a presymptomatic child with a heritable predisposition to cancer has the potential to improve survival and minimize morbidity by allowing prospective monitoring for tumor formation and often life-saving prophylactic surgeries or other preventive measures. This information can also benefit children who already have cancer, as it can influence choice of the most appropriate or least toxic cancer-directed therapy. For example, one should avoid the use of radiation therapy in children with hereditary RB or LFS, as these children are at increased risk of developing secondary irradiation-induced malignant disease due to their constitutional genetic mutations. Similarly, in a child with a WT predisposition syndrome, it is recommended that a renal tumor be removed using nephron-sparing surgery and not total nephrectomy. Because the remaining kidney tissue remains at risk for tumor formation and could thus become the target of future surgical procedures, it is deemed advisable to leave as much healthy kidney in place as possible. Below, we review some of the salient principles of tumor surveillance and cancer risk reduction for children with heritable predisposition to cancer.

Principles of Tumor Surveillance

Cancer surveillance guidelines exist or are being developed for several conditions predisposing to childhood cancer. The primary goal of surveillance is to detect cancers at the earliest and most curable stage. For this reason, cancer surveillance protocols are best suited for solid tumors, where survival is often linked to the size and extent of spread of the tumor at diagnosis. Tumors identified in individuals undergoing regular monitoring may be smaller. As a result, surveillance allows for less invasive surgical procedures and can also reduce or eliminate the need for additional chemotherapy and/or irradiation. However, surveillance can also be complicated by the possibility of false-positive results, which often lead to worry about cancer, excess rates of follow-up imaging and/or biopsy, and possibly increased costs of care.

Several factors must be taken into account in the development and implementation of a cancer surveillance protocol. First, there must be a benefit for early cancer detection in an individual undergoing monitoring (i.e., there should be an effective treatment available and preferably also demonstration that early detection improves outcome). Second, the age-specific tumor risks for syndromes predisposing to cancer must be known and deemed high enough to warrant surveillance (generally, a tumor incidence of ≥5% is considered sufficiently high to initiate monitoring). This information helps to identify candidates for surveillance, when it should be initiated, and how long it should be continued. The surveillance method(s) and interval between specific tests must also be carefully considered in light of the specific tumor risks and growth rate associated with a given syndrome. Ideally, surveillance methods should be readily available, safe, and have high sensitivity and specificity. Whenever possible, screening tools that involve no or minimal irradiation should be used, as patients with hereditary cancer syndromes may be at increased risk to develop irradiation-induced cancers (as is the case for hereditary RB, LFS, ataxia telangiectasia, and other genetic syndromes associated with defects in DNA repair).

Cancer Prevention Strategies

For some syndromes, early identification of at-risk children allows for the elimination or dramatic reduction of cancer risk through prophylactic surgery. MEN2 and FAP are excellent examples, where removal of the at-risk organ may be considered early in a patient's lifetime to prevent the development of thyroid or colorectal cancer, respectively. In MEN2, there is a nearly 100% lifetime risk for MTC, an aggressive type of thyroid cancer with a high metastatic potential. As a result, it is recommended that individuals with MEN2 undergo prophylactic thyroidectomy, a procedure that has greatly reduced the likelihood of developing MTC.[63] It should be noted that while all individuals with MEN2 are at increased risk for MTC, there are significant genotype-phenotype correlations that predict the age of thyroid cancer onset, and this information can dictate the appropriate timing for prophylactic removal of the thyroid.[20] In FAP, individuals have a similarly high risk of early-onset colon cancer that nears 100% if colonic polyps are not removed. To prevent colon cancer, affected individuals should undergo colectomy when polyps become too numerous to clinically follow or remove, generally in the late teens to early 20s. Studies of the efficacy of colectomy reveal a significant reduction in colon cancer risk.[6] Due to the morbidities associated with colectomy, alternatives to surgery are being sought. Nonsteroidal antiinflammatory medications such as sulindac and Cox-2 inhibitors reduce polyp formation in adults with FAP[64-66]; however, these medications are currently under examination for use in children with the condition.[67]

SPECIFIC SYNDROMES PREDISPOSING TO CANCER

There currently exist more than 30 genetic conditions that predispose to cancer in which children are at risk for tumor formation (several examples are summarized in Table 42-3). Each of these conditions is typified by distinct clinical and genetic manifestations. For some of these conditions, recommendations regarding genetic testing, surveillance, and management are well established. However, for others these issues are only recently emerging. Here we focus on some of these conditions, including the clinical and molecular features and current recommendations regarding management.

Hereditary Retinoblastoma

Incidence

Hereditary RB is an example of a classic syndrome predisposing to cancer and the first for which the underlying genetic mechanism was recognized. RB is a malignant tumor of the embryonic neural retina that has an

incidence of two to five cases per million children per year and accounts for 3% to 4% of all pediatric cancers.[4] Nonhereditary RB accounts for 60% of cases and is associated with development of unilateral eye tumors at a median age of 22 months.[68,69] The remaining 40% of patients have hereditary RB, which involves both eyes in more than 80% of cases and presents at a median age of 11 months.[68,69] Heritable RB is highly penetrant, with more than 90% of patients developing RB and 0.5% to 15% also developing intracranial tumors of the pineal gland.[70,71] Over the course of their lives, survivors of hereditary RB remain at increased risk to develop second malignant neoplasms, including bone and soft tissue sarcomas, which commonly occur in previously irradiated sites, as well as melanomas and cancer of the lungs, gastrointestinal tract, and bladder.[72]

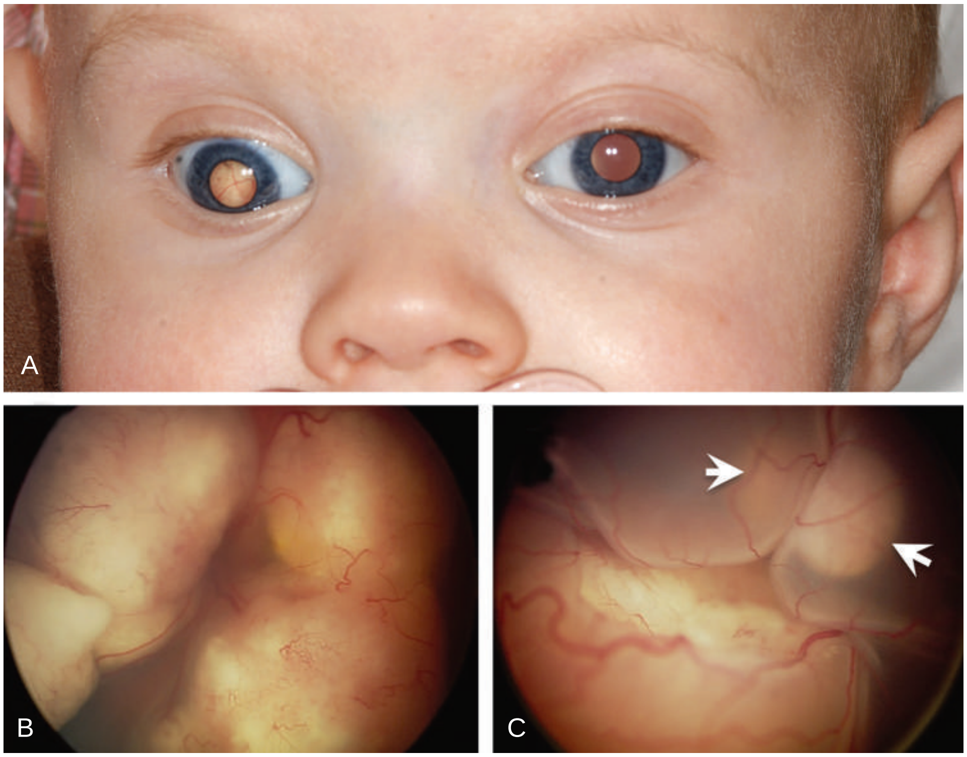

Figure 42-2 A child with hereditary retinoblastoma (RB) with bilateral eye involvement. **A**, The face of an infant with bilateral RB demonstrating bilateral leukocoria, one of the most common presentations for this eye tumor. **B** and **C**, Retinal photographs of this child's ocular tumors, which appear as large white masses. In **B**, the right eye has an advanced-stage (group E) tumor. In **C**, the left eye has a large (group D) tumor with evidence for subretinal seeding (*arrows*).

Genetics

RB is caused by mutations in *RB1*, which resides at chromosomal locus 13q14.[10] *RB1* encodes the RB protein (pRB), a potent tumor suppressor that regulates cell growth by inhibiting the function of the E2F family of transcription factors and preventing inappropriate S-phase entry. pRB also regulates cellular glucose tolerance, mitogenesis, glutathione synthesis, and the expression of genes involved in carbon metabolism.[73] When both RB1 alleles are mutated within a developing retinal cell, pRB expression and/or function are diminished, cell division proceeds in a dysregulated manner, and, ultimately, RB tumors form.

In patients with nonhereditary RB, both RB1 gene copies are mutated within a single postzygotic retinal cell. In contrast, patients with hereditary RB harbor one mutated RB1 allele within the germline. This mutation is inherited from a similarly affected parent in 10% to 20% of cases.[69] In the remaining cases, the RB1 mutation arises de novo within one of the parent's gametes[74] or a cell of the developing embryo. Mutation of the remaining RB1 allele occurs somatically. Genetic testing for germline RB1 gene mutations can identify mutations in more than 90% of individuals with hereditary disease.[75,76] While most patients can be identified clinically due to the presence of multifocal or bilateral eye tumors and/or a positive family history, 10% to 15% of patients have single eye tumors and no family history of RB. These latter factors make them indistinguishable from those with the sporadic form of disease. The identification of RB1 mutations in unilateral patients enables appropriate primary eye tumor treatment as well as initiation of surveillance for involvement of the pineal gland and later second cancers. Identification of a germline RB1 mutation in any child with RB also allows for presymptomatic testing of other family members, including siblings who may not yet have developed RB but carry a mutated RB1 gene copy, as well as children of RB survivors.

Tumor Risks and Surveillance

Individuals harboring germline RB1 mutations are at greatly increased risk to develop bilateral RB tumors, generally during the first 5 years of life (Fig. 42-2). During this time period patients are also at increased risk to develop tumors involving the pineal gland (so-called trilateral RB). Later in life, individuals with hereditary RB can develop second malignant neoplasms. While the risk for these cancers is greatest in those treated with external-beam radiation therapy, nonirradiated long-term survivors of hereditary RB have an approximately 10% to 15% risk of developing one or more second malignant neoplasms[77]

The early detection of eye tumors has been shown to significantly increase ocular retention and preserve vision.[78] Therefore, it is recommended that children at risk for RB be examined by fundoscopy beginning 1 to 2 weeks after birth and then every 2 weeks until the age of 3 months.[78] Subsequently, examinations should be performed under general anesthesia until the age of 4 to 5 years.[79] The frequency of examination depends upon the age of the patient, with examinations recommended every 2 months during the first year of life and then gradually spaced to every 6 months during the fourth to fifth years of life.[79] A study by Abramson and colleagues[80] showed that patients with a positive family history who received ophthalmologic examinations from birth had an overall survival rate of 93.2% and an ocular retention rate of 67.7%. This is in contrast to patients who did not receive screening, whose survival rate measured 87.4% and ocular retention rate only 38.2%. In addition to increased ocular retention, early screening and close follow-up results in a long-term visual acuity measuring between 20/20 and 20/40 for approximately 90% of patients with hereditary disease.[78] To screen for pineal tumors, it is recommended that children undergo magnetic resonance imaging (MRI) examination of the brain every 6 months until the age of 5 years.[71] Screening in this manner successfully identifies tumors when they are smaller and has been reported to increase the 5-year survival rate from 0% to 27%.[71] While the basis for ocular and pineal gland surveillance is well established, it remains unclear whether monitoring for second malignant neoplasms is of benefit. As a result, monitoring for these tumors is not yet recommended and remains the subject of investigation.

Li-Fraumeni Syndrome

Incidence

LFS is a highly penetrant cancer syndrome first described in 1969 in four families with soft tissue sarcoma and early-onset breast cancer.[81] Since this initial observation, more than 500 families have been reported with complete or partial LFS phenotypes, and it is possible that many more families exist that have not yet been identified. In 1990, it was determined that germline *TP53* mutations were responsible for most cases of LFS.[82] The *TP53* mutation carrier rate has been reported to be about 1 in 5000 births,[23] although the true incidence and prevalence of germline *TP53* mutations are unknown. *TP53* germline mutations are more common in southern Brazil, due to a founder mutation with a high population prevalence of nearly 0.3%.[83-85,86]

Genetics

TP53 encodes p53, which is often referred to as the “guardian of the genome” because it is a critical transcription factor that mediates cellular stress responses and initiates DNA repair, cell-cycle arrest, senescence, and apoptosis. *TP53* somatic alterations have been detected in nearly every type of human cancer, and patients with LFS who harbor a mutated copy of this important cancer-preventing gene are much closer to the threshold of developing cancer in any of their body tissues. Although there are no strong genotype-phenotype correlations, early tumor onset has been reported to be more common in those with nonsense, frameshift, or splice site mutations.[87] Modifiers of tumor risk have included increased burden of copy number variants,[88] shorter telomeres,[89] a single-nucleotide polymorphism at codon 72 (R72) of *TP53*,[90,91] and a single-nucleotide polymorphism (rs2279744) affecting the p53 inhibitor MDM2.[91] As more LFS families are studied, these associations and the genotype-phenotype correlations will be more clearly elucidated.

Over the years, several classification systems have been developed to help identify possible LFS families and determine those to whom *TP53* genetic testing should be offered (Table 42-4). Currently, *TP53* mutations are

TABLE 42-4 Clinical Classification Schemes for Li-Fraumeni Syndrome

Classification Criteria	Description
Classic Li-Fraumeni syndrome (LFS)	Proband with sarcoma diagnosed before 45 years of age and First-degree relative with cancer diagnosed before 45 years of age and First- or second-degree relative on same side of family with cancer diagnosed before 45 years of age or sarcoma at any age
Chompret classification	Proband with LFS spectrum cancer diagnosed before 36 years of age and At least one first- or second-degree relative on same side of family with cancer (other than breast cancer if proband has breast cancer) diagnosed before 56 years of age or A relative with multiple primary cancers at any age A proband with cancer with a relative with cancer or multiple primaries, two of which are sarcoma, brain tumor, breast cancer, and/or adrenocortical carcinoma, with the initial cancer occurring before 46 years of age, regardless of family history A proband with adrenocortical carcinoma or choroid plexus carcinoma at any age, regardless of family history
Birch classification	Proband with any childhood cancer or sarcoma, brain tumor, or adrenocortical carcinoma diagnosed before 45 years of age and First- or second-degree relative with typical LFS cancer (sarcoma, breast cancer, brain tumor, leukemia, or adrenocortical carcinoma) diagnosed at any age and First- or second-degree relative on same side of family with any cancer diagnosed before 60 years of age
Eeles classification	Two first- or second-degree relatives with LFS-related malignant disease (sarcoma, breast cancer, brain tumor, leukemia, adrenocortical carcinoma, melanoma, prostate cancer, or pancreatic cancer) at any age

identified in 70% or more of patients who meet the strict diagnostic criteria for LFS. The mutation detection rate drops to 20% in families classified as "Li-Fraumeni–like," who exhibit some but not all of the features associated with LFS (such as very early onset or multiple primaries).[92] Even without an identified *TP53* mutation, cancer-prone families with an LFS pedigree are considered to be at high risk for an inherited cancer syndrome, and it is recommended that members of these families be monitored carefully for early cancer development using modalities currently in place for those with genetically verified LFS.

Tumor Risks and Surveillance

Patients with classic LFS are at risk for nearly every type of cancer, and the lifetime cancer risk is extraordinarily high, with a 68% risk in men and 93% risk in women.[93] Patients with LFS most commonly present with breast cancer (nearly 30% of patients), soft tissue sarcomas (<20%), brain tumors (<14%), osteosarcomas (12% to 14%), and ACCs (6.5% to 10%).[23,85,87,93] In children, the tumors most strongly associated with LFS include ACC, CPC, rhabdomyosarcoma presenting before 3 years of age, and osteosarcoma presenting before 5 years of age.[23,27,87] Recently, *TP53* germline mutations have been described in nearly half of patients with hypodiploid pre-B acute lymphoblastic leukemia,[94] most notably those children whose leukemia cells are considered "low hypodiploid" and contain a median of 32 to 39 chromosomes. A germline *TP53* mutation was also described in an additional kindred with familial transmission of acute lymphoblastic leukemia.[95] Nearly half of cancers in LFS present before 30 years of age.[93] The phenomenon of genetic anticipation has been observed in LFS, with a decrease in age and increase in cancer onset in successive generations.[96] Subsequent tumors also are an issue in LFS, with more than an 80-fold relative risk for a second malignant neoplasm in patients with their first cancer under the age of 20, a 10-fold relative risk if diagnosed between 20 and 44 years, and a 1.5-fold relative risk if diagnosed at over 45 years.[97]

The recommendations for cancer surveillance in patients with LFS are emerging, although no formal guidelines for affected children are in place at this time. For *TP53* mutation carriers, a healthy lifestyle with avoidance of ionizing radiation and DNA-damaging agents is encouraged. Annual dermatology visits are recommended, along with avoidance of unprotected sun exposure. Annual physical examinations are also recommended, with careful attention to the thyroid and abdomen for masses and a neurologic examination for indication of brain tumors. For adults, colonoscopy is recommended beginning at age 25 years; if there is a family history of colorectal cancer, the patient can consider screening at an age 5 to 10 years younger than the earliest age at which colorectal cancer has been diagnosed in other family members. For women, annual mammograms and breast MRI are recommended beginning at age 25 years, with these procedures alternated so that the breasts are screened every 6 months. The cost versus benefit of mammography in this high-risk population is still being explored, and these recommendations may change in the future.[98]

Currently, studies are ongoing to determine whether newer radiologic approaches, alone or in combination with other screening measures, are effective in detecting tumors in patients with LFS. One study of rapid whole-body MRI combined with other imaging and laboratory measures has reported increased survival rates in patients with LFS,[99] and this now can be considered an option for surveillance (Fig. 42-3). Additional measures being offered include abdominal ultrasound (to screen for ACC or other intraabdominal tumors), assessments of complete blood count (to detect leukemia), and measurements of adrenal hormones (to screen for ACC). Although it has not yet been definitively proven that surveillance is beneficial, many practitioners will test for *TP53* mutations in order to begin a tumor surveillance program in children who are determined to be at increased cancer risk. Cancers identified in LFS patients can be treated according to standard protocols, although the avoidance of agents that might damage DNA (e.g., exposure to ionizing radiation) is recommended due to the increased risk for second malignant tumors in this population.

WT1-Related Wilms Tumor Predisposition Syndromes

Incidence

Wilms tumor (WT, also known as nephroblastoma) is the most common renal tumor of childhood, accounting for 8% of all pediatric cancers[100] and 95% of pediatric renal cancers.[101] As many as 10% of WTs develop in the setting of a hereditary predisposition, where it is estimated that up to 5% of tumors are caused by germline mutations in the *WT1* tumor suppressor gene.[102] As with other predisposition syndromes, children with germline *WT1* mutations are more likely to present with bilateral kidney involvement[103] and at a younger-than-expected age.[100] Patients may also exhibit a variety of nononcologic clinical manifestations.[13]

Genetics

The *WT1* gene, located at chromosomal locus 11p13, encodes a zinc finger transcription factor that regulates mesenchymal to epithelial transition in embryonic renal and genitourinary development[104] and thus functions as a tumor suppressor gene.[105] The *WT1* gene consists of 10 exons, which encode an N-terminal proline and glutamine-rich transactivation domain, and a C-terminal zinc-finger domain involved in DNA binding.[106,107] Loss of heterozygosity at 11p13 in WT samples suggests a key role as a tumor suppressor,[108] and numerous constitutional mutations in *WT1* have been described in association with familial WT.[100] In cases of *WT1*-associated WT, a second mutation in either CTNNB1 or *IGF2* is often also required for oncogenesis.[101]

Tumor Risks and Surveillance

Patients harboring a germline *WT1* mutation develop WT in the context of several distinct clinical syndromes (Table 42-5), including WT, aniridia, genital anomalies, and retardation (WAGR), Denys-Drash syndrome (DDS),

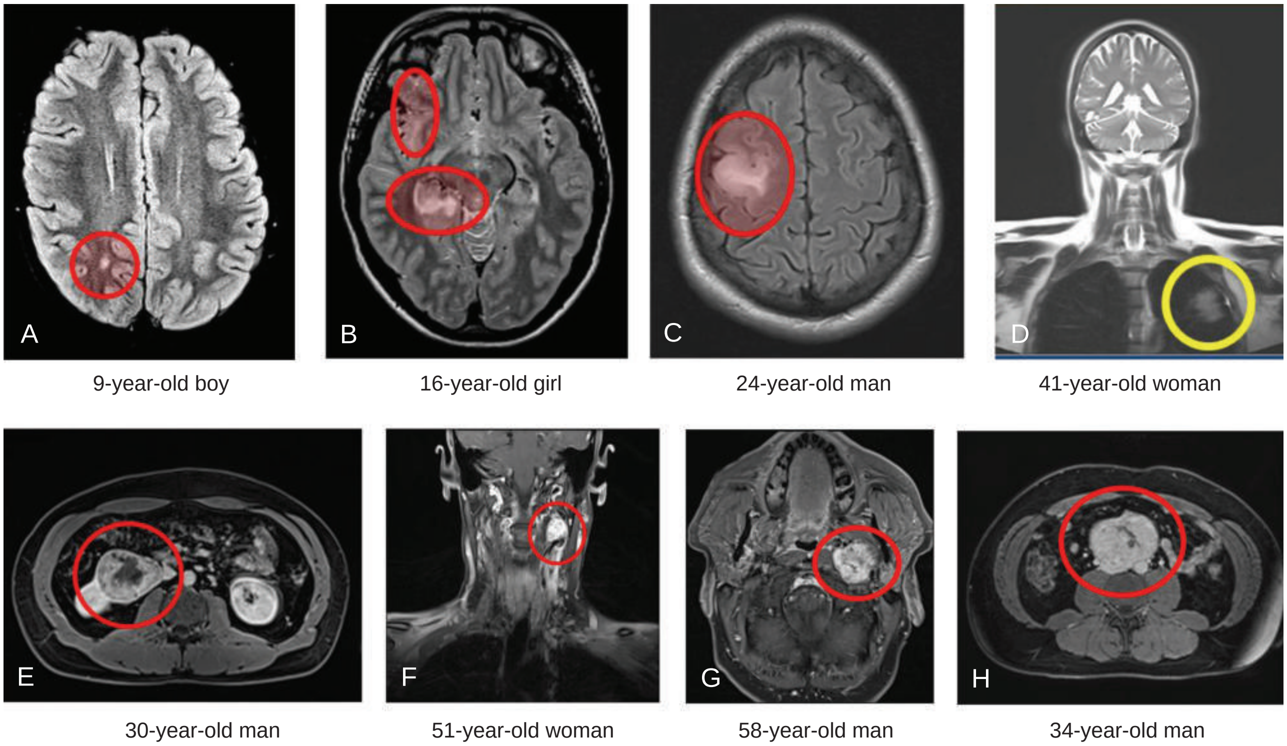

Figure 42-3 Tumors identified by magnetic resonance imaging (MRI)-based surveillance of asymptomatic TP53 and SDHB mutation carriers. **A** to **D**, Examples of lesions in *TP53* mutation–positive patients with Li-Fraumeni syndrome. **A**, Unknown lesion, followed regularly on brain MRI. **B**, Diffuse astrocytoma (World Health Organization [WHO] grade II), resected. **C**, Diffuse fibrillary astrocytoma (WHO grade II), resected. **D**, Lung adenocarcinoma, resected. **E** to **H**, Examples of lesions found in patients with hereditary paraganglioma/pheochromocytoma (PCC), who carried mutations in *SDHB*. **E**, Renal cell carcinoma, removed by nephrectomy. **F**, Carotid body tumor, resected. **G**, Carotid body tumor, resected. **H**, PCC in the organ of Zuckerkandl, resected.

and Frasier syndrome (FS). In a large study of WT patients, only 20% with a germline *WT1* mutation did not have associated congenital abnormalities.[103]

Wilms Tumor, Aniridia, Genital Anomalies, Retardation Syndrome

WAGR syndrome is caused by a contiguous gene deletion at 11p13, which leads to the loss of a single copy of *WT1* as well as neighboring genes, including *PAX6*, a transcription factor critical for development of the eye and other neural organs. Haploinsufficiency for WT1 is believed to result in genitourinary abnormalities, which are most notable in males and include hypospadias and undescended testes,[101] as well as an almost 50% risk of developing WT.[109] Haploinsufficiency for PAX6 contributes to the development of complete or partial aniridia. The etiology of the cognitive delay in WAGR syndrome has not been elucidated, though it is likely that haploinsufficiency for genes adjacent to *WT1* are responsible for this finding.

TABLE 42-5 Clinical and Genetic Features of *WT1*-Related Syndromes Predisposing to Wilms Tumor

Syndrome	Genetic Alteration	Molecular Pathogenesis	Wilms Tumor Risk	Clinical Phenotype
Familial Wilms tumor (WT)	*WT1* mutation or deletion	Altered *WT1* function	Variable risk of WT	Nonsyndromic, hypospadias or undescended testes in males
WAGR syndrome	*WT1* deletion	*WT1* haploinsufficiency	~50% risk of developing WT	Aniridia, genital abnormalities, developmental delays, possibility for streak gonads in girls
Denys-Drash syndrome	*WT1* missense mutation	Dominant negative mutation	>90% risk of WT	Development of diffuse mesangial sclerosis, undermasculinized genitalia in 46 XY males
Frasier syndrome	*WT1* splice site mutation	Altered ratio of *WT1* splice forms	5% to 10% risk of WT	Development of focal segmental glomerulosclerosis, gonadoblastoma, undermasculinized genitalia in 46 XY males

Denys-Drash Syndrome

DDS is characterized by the development of WT, renal diffuse mesangial sclerosis, and undermasculinized external genitalia in 46 XY males. It is caused by missense mutations affecting exon 8 or 9 of *WT1*,[103] which lead to the generation of a WT1 protein with impaired DNA-binding capacity. These WT1 mutants function in a dominant negative fashion, and as a result patients with DDS exhibit a very high incidence (>90%) of WT.[13] Furthermore, approximately 74% of patients develop end-stage renal disease within 20 years of diagnosis.[110] While the molecular pathogenesis of the diffuse mesangial sclerosis remains unclear, murine studies have implicated *WT1* in the regulation of podocyte formation,[111] suggesting a central role for *WT1* in lifelong renal homeostasis. Genitourinary abnormalities of varying severity are common in males with DDS, and there is also an increased risk for gonadoblastoma. In contrast, most females with DDS have normal genitourinary development and no risk for gonadal tumors.[112]

Frasier Syndrome

FS is typified by the development of renal focal segmental glomerulosclerosis, gonadoblastoma, and undermasculinized external genitalia in 46 XY males. FS is caused by point mutations in the WT1 intron 9 donor splice site.[113] Normally, distinct messenger RNA (mRNA) isoforms are produced by WT1 as the result of alternative splicing. The intron 9 alternative splice donor site mutation seen in FS leads to loss of three amino acids (KTS, or lysine, threonine, and serine), thus disrupting the normal ratio of WT1 isoforms critical for proper gonadal and renal development. The altered ratio of WT1 isoforms is associated with decreased expression of *SRY* and *SOX9*, which both encode transcription factors required for normal testicular development.[114] Interestingly, most patients with FS do not develop WT; however, a few cases have been reported,[115] with overall estimates for WT of 5% to 10%.[116] Most males with FS, however, have severe genitourinary abnormalities, resulting in a high risk for gonadoblastoma.[112]

The management of children with WT1-associated WT predisposition syndromes involves genetic testing, tumor surveillance, and organ-sparing therapies. It is recommended that children presenting with WT, genitourinary abnormalities, and/or early-onset renal failure be tested for germline *WT1* mutations.[103] Testing should also be considered for patients with bilateral WT without associated abnormalities, although the yield of testing in this instance is lower.[103] Generally, it is not recommended that children with unilateral WT and no associated abnormalities be tested, as the prevalence of *WT1* mutations in these patients is only 1.4%.[100] All children with aniridia should be screened by fluorescence in situ hybridization studies or single-nucleotide polymorphism array, as up to one third of patients will exhibit loss of one copy of *WT1*[117] and thus be at increased risk for WT formation.

As the treatment strategies for WT have become more successful, screening programs are unlikely to affect these outcomes. However, the goal of screening is to promote earlier detection and, thus, easier surgical management, less intensive chemotherapy, and possible avoidance of radiotherapy. Ninety-eight percent of children with *WT1*-associated WT are diagnosed with their tumors by 7 years of age.[118] As a result, it is generally recommended that patients with germline *WT1* mutations undergo kidney surveillance with renal ultrasound examinations every 3 months through the first 7 years of life.[116] Given the increased risk for multifocal and bilateral disease, it is recommended that for those who do develop WT, nephron-sparing surgery be used whenever possible. Newer areas of investigation focus on the use of neoadjuvant chemotherapy to eradicate renal tumors and thereby avoid the use of surgery. Patients with a germline *WT1* mutation are particularly at risk for this end-stage renal disease. Therefore patients should undergo lifelong monitoring of blood pressure and renal function, with early treatment of hypertension and avoidance of nephrotoxic medications.[110]

Hereditary Paraganglioma/Pheochromocytoma Syndrome

Incidence

PGLs and PCCs are neuroendocrine tumors that generally involve the parasympathetic and sympathetic chains or adrenal glands. PGLs are rare in the general population, occurring at an estimated incidence of 1 : 30,000 to 1 : 1 million.[119-121] However, in the presence of an underlying predisposing condition, the tumor rate can be extraordinarily high.[122,123] Toward this end, a recent study demonstrated that 30% and 81% of children with nonmetastatic and metastatic PGLs/PCCs, respectively, carried germline mutations in genes encoding subunits of the succinate dehydrogenase (SDH) complex.[124] In addition to *SDH* genes, germline mutations in *NF1*, *VHL*, *RET*, *TMEM127*, and *MAX* also predispose to PGL/PCC. Therefore, the true incidence of germline mutations in children with these tumors may be even higher than currently estimated.[125]

Genetics

Hereditary PGL/PCC is caused by germline mutations in the *SDHA*, *SDHB*, *SDHC*, *SDHD*, and *SDHAF2* genes (collectively *SDHx*), which encode components of *SDH*, a mitochondrial enzyme complex responsible for converting succinate to fumarate as part of the tricarboxylic acid cycle.[126] *SDHA*, *SDHB*, *SDHC*, and *SDHD* encode for proteins that make up SDH, while *SDHAF2* encodes for SDH assembly factor 2, a protein needed to assemble the SDH proteins into a fully functioning complex.[16] Mutations in the *SDHx* genes lead to a faulty tricarboxylic acid cycle with increased levels of succinate and subsequent increases in hypoxia-inducible factor (HIF) signaling and histone deregulation. It was recently reported that *SDHx* mutations are associated with a hypermethylator phenotype, which may also contribute to tumorigenesis.[127,128] PGLs are usually benign tumors, but when caused by an *SDHx* mutation, particularly *SDHB*, they exhibit an aggressive metastatic phenotype. The biology behind this clinical difference is not yet known. Hereditary PGL/PCC is inherited in an autosomal dominant fashion; however, *SDHD* and *SDHAF2* are maternally imprinted, with only the children of fathers, not mothers, developing tumors. Nevertheless, mothers can still pass along *SDHD* and *SDHAF2* mutations to their children, who will not develop PGL/PCC but remain at 50% risk to transmit the disease to future generations.

Tumor Risks and Surveillance

The SDHx-related tumor spectrum is broad and includes PGL (*SDHA*, *SDHB*, *SDHC*, *SDHD*, *SDHAF2*), PCC (*SDHA*, *SDHB*, *SDHC*, *SDHD*), gastrointestinal stromal tumors (GISTs) (*SDHA*, *SDHB*, *SDHC*, *SDHD*), papillary thyroid cancer (*SDHB*, *SDHD*), renal cell carcinoma (RCC) and oncocytoma (*SDHB*, *SDHC*), neuroblastoma (*SDHD*), and, most recently, pituitary adenoma (*SDHA*).[93,126,129,130] Patients who develop PGLs as well as GISTs have a condition known as Carney-Stratakis syndrome.[131] In rare instances, PGLs, GISTs, and pulmonary chondromas occur together, in which case they are referred to as the Carney triad. Traditionally, tumors occurring in the context of Carney triad have not been associated with underlying SDHx mutations.[131,132]

Hereditary PGL/PCC has no defining clinical criteria other than a possible family history of *SDHx*-related tumors. Therefore, any child diagnosed with a PGL, PCC, or GIST should undergo genetic testing due to the strong association between these tumors and underlying *SDHx* mutations. Immunohistochemical staining of tumor tissue for *SDHB* protein expression can identify patients at risk for underlying germline *SDHx* mutations.[133,134] Specifically, absent *SDHB* staining indicates that the SDH protein complex is not intact, and this finding may be caused by a mutation in any of the *SDH*-related genes. Clinical laboratories have started to offer *SDHB* immunohistochemical staining to facilitate genetic diagnosis of hereditary PGL/PCC, although the sensitivity and specificity of this test needs to be determined.

Due to the aggressive nature of *SDH*-related tumors, early identification of small tumors in asymptomatic patients may reduce morbidity and mortality. No consensus screening guidelines exist for tumor surveillance, but many clinicians will perform annual physical examinations, blood pressure checks (to detect hypertension due to increased secretion of catecholamines), and blood work for serum metabolites (fractionated catecholamines, including epinephrine, norepinephrine, dopamine; fractionated free metanephrines, including metanephrine and normetanephrine; and chromogranin A).[135,136] Regular imaging can also identify PGL/PCC, and this is especially important for those with non–catecholamine-secreting tumors.[137-140] Common imaging approaches include computed tomography, ^{18}F-fluorodeoxyglucose positron-emission tomography, and [^{123}I]-metaiodobenzylguanidine scintigraphy. Some centers are beginning to use rapid-sequence whole-body MRI, with or without dedicated neck MRI, as a screening measure for individuals with germline *SDHx* mutations (see Fig. 42-3). Recently, the University of Utah published findings showing that this approach has a sensitivity of 88% and specificity of 95% for detecting new tumors compared with isolated biochemical testing, which exhibited a sensitivity of 38% and specificity of 95%.[141] As *SDHx* mutations are increasingly recognized and studied, we will learn more about the genetic, epigenetic, and metabolic alterations linked to cancer and discover novel approaches to tumor prevention and treatment.

Neurofibromatosis Type 1

Incidence

Neurofibromatosis type 1 (NF1) is considered one of the most common inherited cancer predisposition syndromes, affecting 1 in 3000 children.[142,143] NF1 is caused by germline heterozygous inactivating mutations in the *NF1* gene, which is located on chromosome 17 and encodes the protein neurofibromin.[142-144] In addition to cancer, patients with NF1 are at increased risk to develop benign tumors such as neurofibromas and Lisch nodules (iris hamartomas), as well as nononcologic manifestations, including café-au-lait macules and intertriginous freckles (see Fig. 42-1), bone deformities (long bone pseudarthrosis, skeletal dysplasias, scoliosis, osteoporosis), vascular abnormalities, short stature, and neurocognitive delay.[145-148]

Genetics

The *NF1* gene encodes a cytoplasmic protein, neurofibromin, which is mainly expressed in neurons, Schwann cells, oligodendrocytes, and leukocytes. Neurofibromin functions as a tumor suppressor by restricting cell proliferation through its effects on the RAS signaling pathway. Interestingly, there is wide variation in the phenotypic presentation of NF1, even among family members with the identical *NF1* mutation. Szudek and associates[149] examined familial aggregation of NF1 phenotypes in 904 affected individuals from 373 families with NF1 and concluded that unlinked modifying genes are likely to contribute to the distinct presentations.[149] Most recently, Sabbagh and colleagues[150] evaluated phenotypic correlations between affected relatives in 750 patients with NF1 in 275 multiplex families; they also concluded that genetic modifiers unlinked to the *NF1* locus contribute to the variable phenotypic severity observed in NF1. Thus, similar to other hereditary cancer disorders, loss of *NF1* serves as the first hit but the presence of other modifying genes and/or accumulation of tissue-specific second hits may ultimately dictate the phenotype.

Tumor Risks and Surveillance

The tumors that develop in children with NF1 include malignant peripheral nerve sheath tumors (MPNSTs) and astrocytomas (including optic gliomas [OPGs]), and, less commonly, rhabdomyosarcomas and neuroblastomas. Adults with NF1 remain at increased risk for MPNSTs and gliomas, as well as GISTs, somatostatinomas, and PCCs.[151] Half of patients with NF1 develop plexiform neurofibromas, the majority of which grow slowly but can cause significant disfigurement and pain. A small proportion transform to MPNST, which can be aggressive and resistant to therapy.[152-155] OPGs occur in up to 25% of patients and may lead to blindness if left untreated.

OPGs usually present before 6 years of age, although they may not become problematic until later in life as they encroach along the optic pathway.[156-159]

The diagnosis of NF1 is often clinical and based on a patient having at least two or more of the following criteria: (1) six or more café-au-lait macules measuring more than 5 mm in greatest diameter in prepubertal individuals and more than 15 mm in postpubertal individuals; (2) two or more neurofibromas of any type or one plexiform neurofibroma; (3) freckling in the axillary or inguinal regions; (4) an OPG; (5) two or more Lisch nodules (iris hamartomas); (6) osseous lesions such as sphenoid dysplasia or tibial pseudarthrosis; or (7) a first-degree relative (parent, sibling, offspring) with NF1 as defined by the above criteria. The clinical features of NF1 increase with age. Therefore, many children meet the criteria for diagnosis by 8 years.[32,156] Young children who manifest only with café-au-lait macules should be followed closely for development of other manifestations and considered to have NF1 unless proven otherwise.[160]

Surveillance for early cancers remains controversial in NF1.[58,145,161-163] Upon diagnosis, patients should undergo a thorough physical examination with a complete ophthalmologic evaluation (to assess for compromised vision, which could indicate an underlying OPG) and developmental assessment. Currently, some institutions order baseline and annual head MRIs to screen for OPGs. Other institutions order MRIs only if patients are symptomatic or if visual or central nervous system abnormalities are detected. Avoidance of radiation therapy is encouraged in patients with NF1 as this treatment may be associated with a higher risk for developing subsequent MPNSTs.[153,164]

Von Hippel–Lindau Syndrome

Incidence

Von Hippel–Lindau syndrome (VHL) is an autosomal dominant disorder caused by mutation of the *VHL* gene, which resides at chromosomal locus 3p25.5. VHL is a rare disease, with a prevalence of 1:36,000 live births and an estimated de novo mutation rate of 1% to 3%.[165,166] VHL is primarily considered to be a genitourinary cancer syndrome because of its strong association with RCC, but as discussed below, several different tumor types are associated with germline VHL mutations.

Genetics

VHL encodes a protein with diverse functions, including activity as an ubiquitin ligase as well as a tumor suppressor involved in transcriptional regulation, posttranscriptional gene expression, apoptosis, and extracellular matrix formation.[166,167] The VHL protein functions as part of a complex that targets other proteins for degradation, including HIF1α-.[168] The fact that it participates in the same pathway that is affected by *SDHx* mutations could explain the clinical similarities between VHL and hereditary PGL/PCC; both are characterized by the development of PGL, PCC, and RCC. It is also proposed that VHL's involvement in HIF1α signaling might explain the tendency of patients to form highly vascularized tumors such as hemangioblastomas.[166]

Tumor Risks and Surveillance

VHL is associated with an increased risk of developing benign as well as malignant tumors, including retinal angiomas; central nervous system hemangioblastomas; clear cell RCC; pancreatic islet cell tumors; endolymphatic sac tumors of the inner ear; renal, pancreatic, and epididymal cysts; PGLs; and PCCs. Of these tumors, RCC is one of the most common and develops in nearly 70% of VHL patients by the age of 60 years. Although RCC is common, it is rarely the first tumor to present.[169] In fact, over a third of patients initially present with cerebellar hemangioblastomas decades prior to RCC.[170] Unfortunately, most VHL patients succumb to RCC, the leading cause of mortality in this disorder.[165,169] Somatic *VHL* mutations are found in inherited and sporadic RCC, and are thus recurring drivers of RCC formation.[171]

Any patient who presents with a VHL-related tumor becomes a candidate for *VHL* genetic testing. Asymptomatic children born to a parent with VHL should be tested within the first year of life, given the 50% risk for inheriting the syndrome and the importance of early intervention. *VHL* germline mutations are typically identified in close to 100% of affected individuals, making the genetic test a very reliable one.[172] VHL is typified by strong genotype-phenotype correlations, which can guide the approach to genetic testing and/or screening.[167,173] For example, the VHL "type 1" phenotype lacks PCCs and is associated with *VHL* deletions, insertions, and truncations. The VHL "type 2" phenotype presents with PCCs and is associated with *VHL* missense mutations. "Type 2A" lacks RCC and pancreatic cysts and is associated with specific missense alterations, including the pathogenic *VHL* Y98H, Y112H, and V116F variants. "Type 2B" patients develop RCC and pancreatic cysts, and harbor R167Q and R167W variants. Finally, VHL "type 2C" is associated with PCC only, and is associated with the V155L, R238W, and L188V variants of *VHL*.

Although no evidence-based guidelines exist, many clinicians follow a similar protocol for tumor surveillance. In affected individuals, ophthalmologic examinations should be initiated by 5 years of age or earlier to examine for retinal angiomas. In those at risk for PGL or PCC, plasma catecholamines and metanephrines should be measured annually, along with regular blood pressure monitoring and abdominal ultrasound examinations starting before the age of 10 years. Rapid whole-body MRI may be useful as a means of locating various tumors; however, this approach has not yet been systematically evaluated in VHL. Audiology assessments are suggested to occur every 2 to 3 years starting at age 5 to assess for the presence of endolymphatic sac tumors. In those with hearing loss, tinnitus, or vertigo, hearing evaluation and/or MRI scans should be completed annually. MRI of the brain and spine is recommended to commence around midadolescence to assess for the presence of central nervous system hemangioblastomas, and close neurologic examinations starting at birth and continuing throughout life are also recommended. Collectively, these approaches have proven to be effective in VHL, where they have greatly decreased morbidity and increased life expectancy for affected children and adults.[174]

Beckwith-Wiedemann Syndrome and Isolated Hemihyperplasia

Incidence

BWS is an overgrowth syndrome characterized by macrosomia, neonatal hypoglycemia, abdominal wall defects (omphalocoele, umbilical hernia), hemihyperplasia, macroglossia, ear anomalies, and increased risk for tumor formation.[175] BWS is estimated to affect 1 in 13,700 live births, with 85% of cases being sporadic and 15% familial.[175] Approximately 7.5% to 10% of BWS patients develop malignancy, most commonly hepatoblastoma (HB) or WT.[175,176] ACC, neuroblastoma, and rhabdomyosarcoma are also rarely encountered.[3,33,63] Atypical teratoid/rhabdoid tumor and PCC have been identified in single case reports but may be coincidental findings.[177-179] Isolated hemihyperplasia (IHH) is defined by asymmetric overgrowth of one or more body parts in the absence of the other clinical findings associated with BWS. IHH may represent part of the clinical spectrum of BWS as, in many cases, it has a similar genetic etiology and profile of cancer predisposition.[180]

Genetics

Multiple genetic and epigenetic abnormalities are observed in patients with BWS or IHH, all of which affect chromosomal locus 11p15.5. Among the genes included this region are *IGF2*, which encodes insulin-like growth factor 2, and *CDKN1C*, which encodes cyclin-dependent kinase inhibitor 1C. These and surrounding genes are "imprinted," or differentially methylated, depending on whether the gene copy is inherited from the mother or the father. As a result, only the maternal or paternal copy is expressed at any given time. The epigenetic aberrations in BWS/IHH lead to hypomethylation, and thus overexpression, of *IGF2*, as well as hypermethylation and, thus, reduced expression of *CDKN1C*.[175,181] The overexpression of growth-promoting genes and inhibition of growth-controlling genes may contribute to the overgrowth and tumor predisposition that occur in BWS/IHH.

Fifty-five percent to 65% of BWS patients have a defect at one of two imprinting control centers that determine methylation of the genes in the region. Paternal uniparental disomy at chromosome 11p15.5, in which a child has two copies of the chromosome or chromosomal region from the father and none from the mother, is the genetic abnormality identified in 20% to 25% of patients with BWS.[175,182] About 5% of patients with sporadic BWS harbor germline mutations in *CDKN1C*, a tumor suppressor gene encoding a cell cycle inhibitor, whereas approximately 40% of familial cases display this defect.[175,182] In total, about 75% to 80% of patients with clinical BWS have identifiable constitutional genetic abnormalities. The remaining patients may harbor mutations in novel genes, or be genetic mosaics for alterations in known genes linked to BWS. In mosaicism, the genetic or epigenetic alteration occurs during embryogenesis, with the result that only a subpopulation of cells displays the genetic abnormality. When mosaicism is present, the disease-associated genetic abnormality may be difficult to detect if only a small percentage of cells is affected, or if it is isolated to tissues that are not as easily sampled as the blood.

Tumor Risks and Surveillance

Cancer screening recommendations for patients with BWS or IHH are aimed primarily at detecting HB and WT. Although the incidence of neuroblastoma is higher in patients with BWS than in the general population, it is not considered high enough to warrant screening. Screening should be used for all patients with a clinical diagnosis of BWS or IHH, even if no underlying molecular abnormality is identified. Screening for HB begins when the diagnosis of BWS is made or suspected. It is recommended that patients undergo abdominal ultrasound examinations every 3 months, as well as serial evaluations of serum alpha-fetoprotein (AFP), as AFP is typically increased in patients with HB and thus serves as a very sensitive tumor marker. Although the timing of when to obtain AFP levels remains a subject of debate, it is generally recommended that levels be measured at a minimum of every 3 months.[183] AFP levels tend to be higher in patients with BWS, even in the absence of HB. In addition, levels tend to decrease more slowly over time.[183] Therefore, if the initial AFP level is elevated but there is no abnormality on ultrasound or other imaging, the test may be repeated in 4 to 6 weeks. If the levels are falling, they may be rechecked every 4 to 6 weeks until they return to normal. If the initial elevation is accompanied by a radiologic abnormality, if it fails to fall, or if it exponentially increases, the patient should be referred to an oncologist for further evaluation. Screening for HB can be discontinued at age 4 years as the majority of these tumors develop before this time.

Screening for WT consists of serial ultrasound examinations every 3 months from the time of diagnosis until the age of 8 years. In the first 4 years, the abdominal ultrasound performed to screen for HB is also used to evaluate for renal masses.[184] After age 4 years, imaging may be limited to renal ultrasound, which is faster and less expensive than abdominal ultrasound and does not require that the child fast for the examination. For HB and WT screening, ultrasound is favored over MRI or computed tomography as it is widely available, is noninvasive, leads to no radiation exposure, only rarely requires sedation, and is generally faster and less expensive.

There is increasing evidence to suggest that within the spectrum of BWS and/or IHH, distinct molecular abnormalities confer different risks for tumor development. For example, paternal uniparental disomy and abnormalities at the imprinting control center 1 have the highest risk of tumor development, whereas mutations of *CDKN1C* may not increase a child's risk for malignancy.[62,182,185,186] However, these genetic findings have not yet been used to direct decisions in most screening programs. It is likely, however, that future screening programs will be more precisely designed to take into account the particular risks related to the underlying genetic abnormality.

Data pointing to the benefits of screening in BWS are sparse but encouraging. Choyke and associates[187] report that patients with BWS or IHH who did not undergo screening had an increased rate of high-stage WT (stage III or IV) compared with patients who underwent screening. A report from the National Wilms Tumor Study Group examining 4669 children between 1980 and 1995 found that 1.1% of children with WT had BWS.[188] Interestingly, the children with BWS were diagnosed at younger ages (mean 28 months) than children without BWS (mean 44 months) and with lower-stage WT (71.7% of BWS patients with stage I or II tumors vs. 55% of non-BWS patients). Furthermore, none of the BWS patients presented with metastatic disease, compared with 12% of the non-BWS children. It is not possible to discern how much these differences were affected by screening. Nonetheless, it remains feasible that some of them were due to the positive effects of the monitoring for tumors in this population. Few studies exist evaluating the efficacy of screening for HB, although case reports document presymptomatic detection of tumors in some BWS patients.[189]

Rhabdoid Tumor Predisposition Syndrome

Incidence

Rhabdoid tumors are rare, highly aggressive malignant growths that generally present in infancy or early childhood[190] and are most commonly found in the kidney or central nervous system.[191] The annual incidence of rhabdoid tumors in children under 15 years of age in the United States is 0.19 per million for renal tumors, 0.89 per million for central nervous system tumors, and 0.32 per million for tumors involving other sites (SEER data, 2011). The characteristic somatic genetic abnormality and the primary initiating event includes mutation of the *INI1/SMARCB1* gene located on chromosome 22q11.2.[192]

Genetics

SMARCB1 is part of a chromatin-remodeling complex involved in regulating gene expression, including genes involved in cell cycle control, DNA repair, and differentiation.[193] Both alleles must be inactivated in order for a tumor to arise, consistent with its function as a tumor suppressor gene. Approximately 35% of rhabdoid tumor patients have germline *INI1/SMARCB1* alterations.[194] While the majority of germline mutations are de novo, families with rhabdoid tumor predisposition have been reported in which multiple siblings have been affected. In rare cases, a parent is an unaffected carrier, and can have multiple children with rhabdoid tumor before the condition comes to the attention of a clinical geneticist. Additionally, there have been reports of families in which some members were diagnosed with schwannomatosis, a disorder in which an individual develops two or more benign tumors of the nerve sheath, commonly referred to as schwannomas, while others developed rhabdoid tumors.[194] Most cases of familial schwannomatosis are associated with germline *INI1/SMARCB1* mutations.[10,27,195,196] The penetrance and expressivity of *INI1/SMARCB1* abnormalities are under investigation, and may vary with the specific genetic mutation.[194]

Tumor Risks and Surveillance

The major tumor risk in rhabdoid tumor predisposition syndrome (RTPS) is for the development of renal or extrarenal rhabdoid tumors, which generally have a very aggressive phenotype. In National Wilms Tumor Study Group trials, patients with stage I or II renal rhabdoid tumors had an overall survival rate of 42% at 4 years; those with stage III, IV, or V disease fared less well, with a survival rate of about 16% when evaluated as a group.[190] For those with central nervous system disease, the prognosis is comparably dismal, with a registry review identifying a median overall survival time of 16.75 months.[197] Event-free survival appears to be better in patients with gross total resection compared with those who had subtotal resections of their central nervous system tumors.[197] Thus, if central nervous system tumors were detected earlier, they might be more easily resected and the outcome might be improved. Individuals with RTPS have also been reported to develop multiple schwannomas and meningiomas later in life.[194]

Currently, there are no standard recommendations for surveillance in patients with RTPS. Experts in the field have suggested that patients have thorough physical and neurologic examinations as well as head ultrasound imaging studies monthly during the first year of life to detect the presence of central nervous system tumors. It is also suggested that patients undergo abdominal ultrasound imaging every 1 to 3 months to assess for the presence of renal lesions. After age 4 years, the risk of developing a rhabdoid tumor rapidly declines, and at this point one could consider periodic screening using whole-body MRI. Although there are as yet no studies to confirm the benefit of screening patients with germline *INI1/SMARCB1* mutations, the aggressive natural history of the disease, apparently high penetrance, and well-defined age of onset for central nervous system rhabdoid tumors suggest that screening could prove beneficial. Given the potential survival benefit of surgically resectable disease, it is reasonable to postulate that early detection might improve overall survival rates.

DICER1-Related Tumor Predisposition Syndrome

Incidence

PPB is a rare cancer of embryonal lung tissue, which presents in infancy or early childhood. The first known case was reported in 1945, and the term PPB was proposed in 1988 to describe a range of rare pulmonary and pleural tumors made up primarily of fetal tissues.[198] Over 50 cases have been described, with a median age of 34 months at diagnosis.[199] Hereditary PPB has been observed in a small number of families worldwide, and in 2009 germline *DICER1* mutations were identified as the cause of hereditary PPB.[200] Since this discovery, germline mutations in *DICER1* have been implicated in up to 60% to 70% of PPB cases. Furthermore, careful review of *DICER1*-mutation–positive individuals and families reveals that there are many additional tumors associated with germline *DICER1* mutations, including cystic nephroma, ovarian Sertoli-Leydig cell tumor, embryonal rhabdomyosarcoma, intraocular medulloepithelioma, and supratentorial primitive neuroectodermal tumor.[201]

Genetics

The *DICER1* gene, located at 14q32.13, encodes a cytoplasmic endoribonuclease, which cleaves precursor molecules into microRNAs (miRNAs) that subsequently modulate cellular mRNA expression.[201] Impaired miRNA processing decreases the posttranslational regulation of mRNAs, and germline *DICER1* mutations have recently been shown to promote tumorigenesis via this mechanism.[202] Interestingly, all individuals with familial PPB show haploinsufficiency at 14q32.13 due to germline mutations affecting a single *DICER1* allele.[201] Studies of zebrafish[203] and mice[204] suggest that *DICER1* haploinsufficiency with retention of a single wild-type allele is sufficient for cancers to develop. Perturbations in miRNA concentrations have been implicated in studies of many human cancers, including lung, breast, ovarian, and skin cancers, with diverse and unclear associations between defects in miRNA processing and tumor phenotype depending on the tissue and mutation studied.[205] Consistent with this observation, several recent studies have implicated somatic mutations in *DICER1* in a variety of adult solid tumors.[206,207] Further translational studies will be necessary to explain the exact cause of miRNA-mediated oncogenesis, but it seems likely that miRNA dysregulation represents a new and important pathway in tumor formation.

Tumor Risks and Surveillance

DICER1 syndrome should be considered and clinical gene testing pursued in patients who present with PPB, cystic nephroma, ovarian Sertoli-Leydig cell tumors, embryonal rhabdomyosarcoma, intraocular medulloepithelioma, supratentorial primitive neuroectodermal tumor, or multinodular goiter. In a large retrospective cohort, 11 of 14 (79%) PPB cases, 2 of 3 (67%) cystic nephromas, and 3 of 6 (50%) cases of ovarian Sertoli-Leydig cell tumor were associated with germline *DICER1* mutations.[18] *DICER1* mutations are inherited in an autosomal dominant manner with variable expressivity and incomplete penetrance.[18] A negative family history does not exclude the diagnosis, especially in patients with typical tumors due to de novo germline *DICER1* mutations.

Since *DICER1* syndrome has been only recently described, the understanding of its phenotype and associated tumor risks is evolving. As a result, there are not yet consensus guidelines for surveillance among individuals harboring *DICER1* mutations. In cross-sectional studies, many individuals harboring a *DICER1* mutation do not develop cancer.[18] Given the rare and varied nature of malignant disease associated with *DICER1* germline mutations, individual practitioners will need to account for penetrance, age of tumor onset, clinical impact of early diagnosis, and risk of false-positive screening tests when weighing the risks and benefits of surveillance. Once PPB develops, complete surgical resection (often combined with adjuvant chemotherapy) is indicated and can lead to cure.[199] The overall 5-year survival rate in a cohort of 50 PPB patients was 45%,[13] although there was significant biologic variability within the cohort. A recent European review of 65 cases of PPB reveals that stage, grade, and degree of resection were highly correlated with survival,[208] suggesting that screening and early detection may indeed improve patient outcomes. Patients with *DICER1* mutations warrant close follow-up, and patients and their physicians should remain vigilant for changes in respiratory function, alterations in menses, and development of goiter, as each of these manifestations can herald the development of malignancy in this high-risk patient population.

Constitutional Mismatch Repair–Deficiency Syndrome

Incidence

CMMR-D (also known as CoLoN [Colon tumors and/or Leukemia/Lymphoma and/or Neurofibromatosis features],[210] childhood cancer syndrome,[211] and Lynch III syndrome[212]) is a recently described predisposition syndrome associated with the development of several different types of cancer, and sometimes multiple cancers, in children.[213] CMMR-D is caused by homozygous or compound heterozygous germline mutations in the genes that function in DNA mismatch repair (MMR), including *MLH1*, *MSH2*, *MSH6*, and *PMS2*. Individuals who carry a heterozygous mutation in one of these genes have a condition known as hereditary nonpolyposis colon cancer, or Lynch syndrome [LS]), which predisposes to many cancer types, including early-onset colorectal cancer, endometrial cancer, and ovarian cancer, with an average age of onset of cancer in the 40s or 50s. CMMR-D was first described in two consanguineous LS families in which the children were noted to have features of NF1 and early-onset hematologic and gastrointestinal malignancies.[214,215] To date, about 100 cases have been reported[216,217]; however, the exact incidence of CMMR-D is not known. In addition to cancer, children with CMMR-D develop café-au-lait macules, axillary and/or inguinal freckling, and Lisch nodules. Due to its similarity to NF1, children may be misdiagnosed as having neurofibromatosis.

Genetics

The normal role of the MMR proteins is to identify and repair small errors, such as base pair mismatches and small insertions and deletions, which occur during DNA replication. Additionally, the DNA MMR system has a role in apoptosis in response to DNA damage. Defective MMR leads to the accumulation of additional mutations, which eventually lead to tumor development. MMR-deficient tumors are often characterized by instability in microsatellites, short repeated sequences of DNA that are highly susceptible to errors during DNA replication. In LS, the second copy of an affected MMR gene is lost during tumor development. Therefore, LS-associated tumors are MMR-deficient and high in microsatellite instability (MSI).

Some genotype-phenotype correlations have been reported in CMMR-D. Individuals with biallelic mutations in *MLH1* or *MSH2* are more frequently diagnosed at younger ages and with hematologic malignant disease compared with individuals who carry mutations affecting *MSH6* or *PMS2*. In contrast, brain and other LS-associated tumors are more common in individuals with *MSH6* or *PMS2* mutations compared with *MLH1* or *MSH2*.[213] There is some evidence that individuals with more severe mutations (deletions or truncating mutations resulting in no functional protein) exhibit a more severe phenotype, with hematologic and brain cancers developing in the first decade of life, compared with individuals with less damaging mutations. These latter individuals are more likely to develop hematologic, brain, and gastrointestinal malignant disease in the second to fourth decades of life.[212,213]

Establishing a molecular diagnosis of CMMR-D is similar to making the diagnosis of LS, which can be accomplished in a stepwise manner beginning with testing for MSI and/or loss of expression of an MMR protein, followed by mutational analysis of the appropriate MMR genes. Because patients with CMMR-D have constitutional MMR deficiency, MSI and lack of MMR protein expression should theoretically be detectable in tumor as well as normal tissue. Interestingly, immunohistochemical staining of tumor was recently shown to be 100% sensitive and specific in diagnosing MMR deficiency, whereas MSI was neither sensitive nor specific and thus did not help in making the diagnosis.[209] If one or more of the familial MMR mutations are already known, it may be possible to proceed directly to genetic testing in the individual in question. It is important to note that diagnostic and genetic testing for this disorder is challenging, and it should be coordinated by professionals with experience in the diagnosis of LS and/or CMMR-D.[212,213,218]

Tumor Risks and Surveillance

The cancers most commonly associated with CMMR-D include hematologic malignant tumors, brain tumors, and LS-associated cancers (most notably, very early-onset gastrointestinal cancer).[209] Less common cancers include neuroblastoma and rhabdomyosarcoma.[212,213,217] In recent reviews, LS-associated cancers (mostly gastrointestinal) accounted for 32% to 37% of all cancers, brain tumors for 32% to 48%, and hematologic cancers for 15% to 24%; 5% to 7% were other types of cancer.[209,213] Multiple primary tumors have been reported in 20% to 40% of patients.[216,217] Age of onset varies by tumor type, with hematologic malignant tumors presenting in early childhood (mean age of onset, 5.5 years), brain tumors presenting in slightly older children (mean age of onset, 8 years), and LS-associated tumors in adolescence and young adulthood (mean age of onset, 15 to 16 years for gastrointestinal and genitourinary tract cancers and 24 years for endometrial cancer). LS-associated tumors may present as a second or third malignancy in patients who survive their initial cancer diagnosis.[213] In one study, gastrointestinal polyps or cancers were the first manifestation of CMMR-D in up to one third of patients.[217]

CMMR-D should be considered for young children who present with hematologic malignant disease, brain tumors, and/or LS-related cancers, in conjunction with: (1) café-au-lait macules and/or other signs of NF1 and/or hypopigmented skin lesions; (2) consanguineous parents; (3) a family history of LS-related cancers; (4) a second malignant tumor; and (5) siblings with childhood cancer. The lack of a family history of LS-related cancers should not rule out the possibility of CMMR-D, as some families could carry less penetrant mutations and thus not meet clinical criteria for a diagnosis of LS.[212,216,219] Because CMMR-D shares clinical features with NF-1, FAP, and LFS, it is important to keep this diagnosis in mind when evaluating children who present with one or more of these features.[213,216,217,220]

Development of a surveillance protocol has been challenging in CMMR-D because of the variety of associated cancers and the possibility of multiple primary cancers. There are currently no standard cancer screening guidelines, although some groups have suggested protocols including surveillance for colon and other gastrointestinal, hematologic, endometrial and ovarian, and other cancers.[217,221] Recently, it was reported that a surveillance protocol including semiannual brain MRI, annual gastrointestinal endoscopy, and blood work every 4 months successfully identified 39 asymptomatic tumors in a cohort of 23 children with CMMR-D, including 2 malignant gliomas, 2 gastrointestinal carcinomas, and 6 cases of polyposis.[209] There are currently very few data regarding the optimal treatment of cancers in patients with CMMR-D. However, clinicians should be aware of the possibility of increased toxicity and reduced efficacy of chemotherapy, as well as increased risk of second primary malignant tumors.[219,222]

CONCLUSIONS, CHALLENGES, AND LOOKING TO THE FUTURE

Since the isolation of *RB1* as the first gene predisposing to cancer, we have experienced tremendous advances in cancer genetics, including sequencing of the human genome and elucidation of DNA, RNA, and the epigenetic landscape of several different cancers. These new data have led to a profound increase in our knowledge of genes that predispose to cancer and the heritable basis of cancer. The characterization of these genes has highlighted critical roles for the encoded proteins in processes ranging from cell cycle control, DNA repair, apoptosis, signaling, miRNA processing, and metabolism. Because many of these predisposing genes are also mutated on a somatic level in a wide array of sporadic cancers, the study of rare cancer syndromes— many of which affect children—has provided invaluable insights into the processes underlying tumor formation.

Along with these advances have come many challenges. For example, we continue to know little about the psychosocial, developmental, and behavioral issues related to the genetic testing of children or adults for heritable predisposition to cancer. We do not yet understand which factors influence the pursuit and uptake of genetic testing by families, whether patients truly understand genetic test results and their implications, how individuals choose to communicate results within their immediate and/or extended families, and how genetic information influences the health-promoting and risk-taking behaviors of children and other family members. For many conditions predisposing to cancer, it is impossible to know when and what types of cancer will occur. This uncertainty makes it difficult to establish effective surveillance protocols. Assessment of the costs and benefits of these protocols is further compounded by the rarity of specific syndromes.

These challenges are only likely to exponentially increase as genetic technologies evolve and are increasingly applied to the clinical setting. Although these technologies will further our knowledge of the pathogenic mutations linked to cancer, they will also reveal many less-damaging variants. In many cases, it may not be readily evident whether these variants influence the expression or function of an encoded protein. Therefore, it will be difficult to know how to react to these results. Will these variants influence disease susceptibility, response to treatment, and/or therapy-associated toxicities? How do these variants cooperate with one another or with environmental factors during the process of tumor formation? As more information is gained and functional assays are developed, variants may eventually be reclassified as benign polymorphisms or disease-causing mutations. Who will be responsible for reanalyzing these data, reporting the updated results, and explaining their implications to clinicians and patients? Finally, how will we translate the increasing body of genetic information to the clinical setting to predict cancer risk, direct tumor screening, and prevent tumors from occurring? Although it is expected that genetic discoveries will enable development of new and more effective therapies or preventive measures, unfortunately we are yet to realize these benefits for the majority of human cancers. Ultimately, the challenge lies in establishing national and international collaborations, where information on these rare, yet informative, syndromes predisposing to cancer can be gathered, integrated, and analyzed to address these important and as yet unanswered questions.

ACKNOWLEDGEMENTS

This work was funded in part by the Grundy Vision of Life Fund at The Children's Hospital of Philadelphia. We thank Dr. Carol Shields for providing the retinoblastoma images shown in Figure 42-2.

   This article provides a review of guidelines and position statements on presymptomatic and predictive genetic testing of children. Reviews special issues to be considered in the testing of children and focuses on particular areas of discussion and disagreement among various guidelines.

54. Michie S, Bobrow M, Marteau TM: Predictive genetic testing in children and adults: a study of emotional impact. *J Med Genet* 38(8):519–526, 2001.

   A study examining the psychological impact of positive genetic test results on adults and children. Psychological responses, including anxiety and depression, were measured in adults and children undergoing genetic testing for FAP. Compares the reactions of children and adults to test results and reviews possible factors affecting psychological outcomes.

61. Riley BD, Culver JO, Skrzynia C, et al: Essential elements of genetic cancer risk assessment, counseling, and testing: updated recommendations of the National Society of Genetic Counselors. *J Genet Couns* 21(2):151–161, 2012.

   Recommendations of the National Society of Genetic Counselors regarding all elements of cancer genetic risk assessment. Reviews the impact of identifying patients at increased risk of developing cancer on cancer surveillance and treatment; cancer risk assessment tools such as family history and cancer risk assessment software programs; when genetic testing should be offered; and elements of informed consent, disclosure of genetic test results, and psychosocial assessment.

81. Li FP, Fraumeni JF, Jr: Rhabdomyosarcoma in children: epidemiologic study and identification of a familial cancer syndrome. *J Natl Cancer Inst* 43(6):1365–1373, 1969.

   This is the original article describing the original cluster of familial cancers that eventually became known as LFS, named after the two coauthors. This article is of historical interest and helps the reader to understand the initial description of an important hereditary cancer syndrome.

82. Malkin D, Li FP, Strong LC, et al: Germ line p53 mutations in a familial syndrome of breast cancer, sarcomas, and other neoplasms. *Science* 250(4985):1233–1238, 1990.

    This article offers the first association between LFS and the TP53 *gene. It helps the reader to learn how genes linked to hereditary cancer syndromes are discovered and described.*

85. Mai PL, Malkin D, Garber JE, et al: Li-Fraumeni syndrome: report of a clinical research workshop and creation of a research consortium. *Cancer Genet* 205(10):479–487, 2012.

    This article describes the creation of a clinical research workshop dedicated to LFS hosted by the National Institutes of Health and a subsequent research consortium. The article highlights the topics discussed at the workshop and the research objectives of the consortium. It can serve as a model for other types of hereditary cancer syndromes.

88. Shlien A, Tabori U, Marshall CR, et al: Excessive genomic DNA copy number variation in the Li-Fraumeni cancer predisposition syndrome. *Proc Natl Acad Sci U S A* 105(32):11264–11269, 2008.

    This article offers a nice example of further molecular characterization of germline DNA in patients with LFS and the identification of copy number variants as genomic modifiers of disease risk. The authors found that excessive copy number variants correlated with patients with LFS and increased risk for cancer presentation.

99. Villani A, Tabori U, Schiffman J, et al: Biochemical and imaging surveillance in germline TP53 mutation carriers with Li-Fraumeni syndrome: a prospective observational study. *Lancet Oncol* 12(6): 559–567, 2011.

    This landmark article offers the first definitive example of the benefits of intensive early tumor screening in patients with LFS. The authors demonstrate that whole-body MRI and targeted laboratory work in patients with LFS resulted in 100% survival at 3 years for patients found to have tumors through screening versus 20% survival in patients without screening.

101. Royer-Pokora B: Genetics of pediatric renal tumors. *Pediatr Nephrol* 28(1):13–23, 2013.

     Focusing on both sporadic and familial WT, this extensive review article summarizes the epidemiology, histology, genetics, and epigenetics of WT and discusses current literature on WT cancer predisposition syndromes. Other types of pediatric renal tumors are also covered in less depth.

105. Pelletier J, Bruening W, Li FP, et al: WT1 mutations contribute to abnormal genital system development and hereditary Wilms' tumour. *Nature* 353(6343):431–434, 1991.

     This describes the original mapping of WT1 *to 11p13 and provides early evidence of the two-hit model of tumorigenesis associated with tumor suppressor genes. These findings also were instrumental in defining the role of* WT1 *in WAGR syndrome and the pathways involved in normal urogenital development.*

123. Pasini B, Stratakis CA: SDH mutations in tumorigenesis and inherited endocrine tumours: lesson from the phaeochromocytoma-paraganglioma syndromes. *J Intern Med* 266(1):19–42, 2009.

     This review summarizes the association between SDH *mutations and tumorigenesis, as well as the different types of* SDH *mutations, and the association of PGLs with several different tumor subtypes, and biologic hypotheses to explain genotype-phenotype correlations. It is a very thorough description and an excellent article for readers interested in learning about the clinical spectrum of* SDH *mutations.*

125. Schiffman JD: No child left behind in SDHB testing for paragangliomas and pheochromocytomas. *J Clin Oncol* 29(31):4070–4072, 2011.

     Reviews the significant hereditary component of PCCs and PGLs, particularly when they are diagnosed in childhood. Discusses the importance of identifying children with these conditions to allow for appropriate surveillance and medical management of both patients and their at-risk family members.

126. Rutter J, Winge DR, Schiffman JD: Succinate dehydrogenase: assembly, regulation and role in human disease. *Mitochondrion* 10(4):393–401, 2010.

     This review describes the spectrum of SDH *mutations, with an emphasis on the biochemistry responsible for the observed clinical phenotypes.*

141. Jasperson KW, Kohlmann W, Gammon A, et al: Role of rapid sequence whole-body MRI screening in SDH-associated hereditary paraganglioma families. *Fam Cancer* 2013. [Epub ahead of print].

     This study is the first to demonstrate that as in LFS, whole-body MRI is a useful modality for identifying tumors in patients with underlying germline SDH *mutations.*

156. Friedman JM, Birch PH: Type 1 neurofibromatosis: a descriptive analysis of the disorder in 1,728 patients. *Am J Med Genet* 70(2): 138–143, 1997.

     This report describes the National Neurofibromatosis Foundation International Database, which is a multicenter collaborative system for collecting information about patients with NF1. It is a nice example of the power and potential of what a multiinstitutional collaboration can do to advance the research field in hereditary cancer syndromes.

173. Chen F, Kishida T, Yao M, et al: Germline mutations in the von Hippel–Lindau disease tumor suppressor gene: correlations with phenotype. *Hum Mutat* 5(1):66–75, 1995.

     This important study helps to explain the genotype-phenotype correlation in patients with VHL mutations. As emphasized by the authors, this information is useful for presymptomatic diagnosis through targeted screening in patients with VHL mutations who are at risk for specific phenotypic presentations.

201. Foulkes WD, Bahubeshi A, Hamel N, et al: Extending the phenotypes associated with DICER1 mutations. *Hum Mutat* 32(12): 1381–1384, 2011.

     In this recent study, researchers review the variety of malignant diseases associated with DICER1 *syndrome in earlier literature. They additionally suggest a new association between* DICER1 *and several malignant diseases and congenital abnormalities based on careful review of seven new families with* DICER1 *mutation.*

209. Bakry D, Aronson M, Durno C, et al: Genetic and clinical determinants of constitutional mismatch repair deficiency syndrome: report from the constitutional mismatch repair deficiency consortium. *Eur J Cancer* 50:987–996, 2014.

     This is a comprehensive description of a cohort of 23 children with CMMR-D, including their clinical presentations, tumor spectrum, genetic data, and results of tumor surveillance.
